Abstract

Joint inversion strategies for geophysical data have become increasingly popular **as they allow for the efficient combination of** complementary information from different data sets. The algorithm used for the joint inversion needs to be flexible in its description of the subsurface so as to be able to handle the diverse nature of the data. Hence, joint inversion schemes are needed that 1) adequately balance data from the different methods, 2) have stable convergence behavior, 3) consider the different resolution power of the methods **used** and 4) link the parameter models in a way that they are suited for a wide range of applications.

Here, we combine **active source** seismic **P-wave** tomography, gravity and magnetotelluric (MT) data in a petrophysical joint inversion that accounts

for these issues. Data from the different methods are inverted separately and are linked through **constraints** accounting for parameter relationships. An advantage of performing the inversions separately is that no relative weighting between the data sets is required. To avoid perturbing the convergence behavior of the inversions by the coupling, the strengths of the constraints are readjusted at each iteration. The criterion we use to control the adaption of the coupling strengths is based on **variations in the** objective functions from the individual inversions. Adaption of the coupling strengths makes the joint inversion scheme then also applicable to subsurface conditions, where assumed relationships are not valid everywhere, because the individual inversions decouple if it is not possible to reach adequately low data misfits for the made assumptions. The coupling constraints depend on the relative resolutions of the methods, which leads to an improved convergence behavior of the joint inversion compared to a setup, where the resolution is not considered.

Another benefit of the proposed scheme is that structural information can easily be incorporated in the petrophysical joint inversion (no additional terms are added in the objective functions) by using mutually controlled structural weights for the smoothing constraints.

We test our scheme using data generated from a synthetic 2-D sub-basalt model. We observe that the adaption of the coupling strengths makes the convergence of the inversions very robust (data misfits of all methods are close to the target misfits) and that final results are always close to the true models independent of the parameter choices. Finally, the scheme is applied on real data sets from the Faroe-Shetland Basin to image a basaltic sequence

and underlying structures. The presence of a borehole and a 3-D reflection seismic survey in this region allows direct comparison and, hence, evaluate the quality of the joint inversion results. The results from joint inversion are more consistent with results from other studies than the ones from the corresponding individual inversions and the shape of the basaltic sequence is better resolved. However, due to the limited resolution of the individual methods used it was not possible to resolve structures underneath the basalt in detail, **indicating** that additional geophysical information (e.g. CSEM, reflection onsets) needs to be included.

Keywords: Joint inversion, adaptive coupling, sub-basalt imaging

1. Introduction

Joint inversions are integrated procedures that simultaneously invert data from different geophysical methods. They **have** become popular in the past decade and there are recent publications about joint inversions in many fields (see Moorkamp et al. (2016) for an overview). Compared to individual inversion of the same datasets resolutions are generally improved and the ambiguities reduced, if the parameters are linked with each other during the inversion stage. The resultant models from joint inversion typically have parameter distributions that are closer to the real distributions of the physical properties in the subsurface, which facilitates subsequent interpretation. However, there are number of problems in joint inversion algorithms; in particular if the involved methods are sensitive to different physical properties (e.g. seismic velocity, density and/or resistivity). This is because:

1. data sets from the individual methods consist of different data types,

15 sensitivity and numbers of measurements, so their influence on the final
 16 model have to be properly balanced during the joint inversion proce-
 17 dure. To find such optimum relative scaling can be difficult and im-
 18 proper scaling results in data from some methods being well-fitted, but
 19 data from other methods being seriously under-fitted (or over-fitted);
 20 2. convergence behaviour is often complex and strongly non-linear for
 21 some methods (e.g. magnetotelluric, control source electromagnetic,
 22 seismic full-waveform tomography) and the convergence path through
 23 the model space of each method is typically different. The convergence
 24 behaviour and path is further complicated by the coupling within joint
 25 inversion. Hence, the joint inversion may get trapped in local minimum
 26 far away from an adequate solution where all methods have reasonable
 27 data misfits;
 28 3. resolution capabilities of the methods differ and usually vary signifi-
 29 cantly with location in the model. Like the balance problem in (1)
 30 above, ignoring these resolution issues in the joint inversion algorithm
 31 may result in a bad data fit for some of the methods, some bias in the
 32 models or slow convergence behaviour;
 33 4. assumptions used to link the different methods (or models), typically
 34 involve some approximations of the petrophysical or structural rela-
 35 tionships that are often not valid for the entire subsurface under in-
 36 vestigation. Too rigid implementation of these links or an improper
 37 choice of assumptions can result in serious and unpredictable errors in
 38 the joint inversion results.

39 For deterministic approaches that are suitable for handling large num-
 40 ber of unknowns and are applicable for problems with time consuming for-
 41 ward calculations, several strategies exist to deal with these problems. To
 42 find adequate relative scaling between the data sets (1st problem), most
 43 joint inversions algorithms consider only weighting that is defined by the
 44 assumed errors of the individual measurements (expressed by the data co-
 45 variance matrix). Other approaches are purely data driven (e.g. Xu, 2009)
 46 or use of multiplicative objective functions to balance the different data sets
 47 (e.g. Abubakar et al., 2009). Some inversion approaches (e.g. Günther and
 48 Rücker, 2006; Paasche and Tronicke, 2007; Bouchedda et al., 2012; Zhu and
 49 Harris, 2015) attempt to overcome this problem by independently inverting
 50 the data from different methods and share information from the parameter
 51 models between the different inversion runs to promote a similarity between
 52 the final models. Such joint inversions are commonly named "cooperative"
 53 and have the advantage that no relative weighting between the data sets is
 54 required.

55 To ensure convergence in deterministic inversions (2nd problem), sev-
 56 eral strategies are proposed that adjust the regularisation strength (Kilmer
 57 and O'Leary, 2001; Vogel, 2002) by applying e.g. L-curve fitting (Hansen,
 58 1993), generalized cross-validation (GCV) (Golub and Van Loan, 1996) or
 59 the discrepancy principle (Morozov, 1966; Vogel, 2002). For joint inversion
 60 e.g. Lelièvre et al. (2012) use a gradually decreasing regularisation that is
 61 determined at every iteration from the relationship between the actual data
 62 misfit and the specified target misfit. Other joint inversion approaches em-
 63 ploy Lagrange multipliers for balancing the coupling constraints that result

64 in a more stable convergence (e.g. Gallardo and Meju, 2004; Gallardo, 2007).

65 The impact of resolution power of the individual methods (3rd problem)
66 can be handled by adjusting cell sizes (Lien, 2013) in the parameter models
67 or using independent and spatially flexible regularization strengths for each
68 parameter model.

69 Structural approaches, which assume that spatial variations in the dif-
70 ferent parameter models are present at the same locations and are simi-
71 larly orientated in space, are considered as valid for many subsurface condi-
72 tions (4th problem) and are widely used (e.g. Haber and Oldenburg, 1997;
73 Gallardo and Meju, 2004; Günther and Rücker, 2006; Doetsch et al., 2010;
74 Molodtsov et al., 2013; Zhu and Harris, 2015). However, there are contri-
75 butions (e.g. Lelièvre et al., 2012) that note that structural links provide
76 a rather weak coupling resulting only in clear improvements compared to
77 individual inversions in regions that are already relatively well-resolved by
78 most of the individual methods; although other publications (e.g. Moorkamp
79 et al., 2013) show that structural joint inversions can provide superior re-
80 sults even in cases when low-resolution methods are involved. In contrast,
81 other assumptions that are more rigorous and less generally valid, e.g. petro-
82 physical coupling using parameter relationships (Lees and VanDecar, 1991;
83 Afnimar et al., 2002; Moorkamp et al., 2011), often impose a strong cou-
84 pling and result in significant improvement even for low resolution methods
85 or in parts of the investigated subsurface volume that are not sampled by
86 all of the methods. Which methods work best for a particular joint inver-
87 sion problem needs to be determined on a case by case basis dependent on
88 the survey design and the geological settings. Some approaches (Colombo

89 and Stefano, 2007; Lelièvre et al., 2010) have developed options to combine
 90 both structural and petrophysical information in the joint inversion. Other
 91 joint inversions either use more generally valid assumptions for petrophysical
 92 coupling by employing flexible parameter relationships that can be modified
 93 during the inversion process (Nielsen and Jacobsen, 2000; Lelièvre et al.,
 94 2012) or use approaches that invert directly for reservoir and rock proper-
 95 ties (e.g. Hoversten et al., 2006; Dell’Aversana et al., 2011). An alternative
 96 way of considering structural information is to use sharp-boundaries in joint
 97 inversions (e.g. Juhojuntti and Kamm, 2015) that allow strong contrasts at
 98 interfaces, but inherently assume that the subsurface consists of a number of
 99 distinct layers, an assumption that is not necessarily true. Finally, several
 100 authors couple data by clustering (e.g. Paasche and Tronicke, 2007; Lelièvre
 101 et al., 2012; Sun and Li, 2013) that can be considered more appropriate than
 102 simplified petrophysical assumptions for some geological conditions.

103 The objective of this paper is the introduction and test of a new joint in-
 104 version strategy, in which we try to mitigate the four problems raised above.
 105 Our scheme *JINV2D* is a cell-based non-linear 2-D joint inversion that com-
 106 bines magnetotelluric (MT), seismic P-wave tomography and gravity data
 107 by using petrophysical information and has been mainly developed to in-
 108 vestigate sub-basalt structures that are often not well-resolved by reflection
 109 seismic data. To avoid relative scaling (1st problem) we use a cooperative
 110 joint inversion in which the inversion steps are performed separately for each
 111 method and the otherwise independent inversions are linked by employing
 112 constraints that account for parameter relationships. Core element of our
 113 proposed joint inversion is an automated adaptive coupling scheme, which

allows for flexible inclusion of these constraints. This adaptive scheme ensures a robust convergence (2nd problem) for all methods and allows the obtained physical parameter models to deviate from the initial assumed parameter relationships, which makes this assumption less rigid (4th problem). Different resolutions of the various methods (3rd problem) are handled by making the behavior of the coupling constraints dependent on the relative resolution power of the methods. Finally, we include a method that allows the exchange of structural information between the parameter models in addition to petrophysical information.

Within the methodology section we first outline our joint inversion strategy. We then focus on a more detailed description of its implementation. The adaptive joint inversion scheme is tested on a synthetic model that is associated with settings that are typical for sub-basalt problems. Finally, we present joint inversion results from a real data example for sub basalt imaging from the Faroe-Shetland Basin, where wide angle streamer seismic, marine MT and marine gravity data are combined.

2. METHODOLOGY - OUTLINE OF JOINT INVERSION STRATEGY

2.0.1. Parametrization

The 2-D grids used for the forward modeling routines are composed of rectangles to which constant velocity, density and resistivities are assigned. Cell sizes are adapted individually for each method to account for numerical accuracy issues and computational efficiency. For the inversion we use a coarser grid created by combining several forward modelling cells, since the

138 presented inversions (independent on the methods) do not resolve the model
139 at the numerical precision required for the forward problem. We choose
140 the same inversion grid for all three methods such that different physical
141 parameters can be easily linked to each other in the joint inversion and the
142 method with highest resolution defines the cell sizes to avoid data mismatches
143 associated with improper discretization.

144 2.0.2. Forward modeling

145 Because standard forward modelling techniques are implemented for all
146 methods we only briefly summarize the routines and refer to the literature for
147 further information. For seismic tomography first-arrival times are computed
148 by an eikonal solver (Podvin and Lecomte, 1991) and afterwards the associ-
149 ated ray-paths are constructed by a steepest descent method (Aldridge and
150 Oldenburg, 1993). For gravity modelling the z-component of the attractions
151 from all cells are calculated for each gravity station and the resulting grav-
152 ity responses are then obtained by summing the contributions from all cells
153 (Bear et al., 1995). Border effects for the gravity due to the finite extent of
154 the 2-D model are avoided by adding semi-infinite horizontal rods at the left
155 and right boundary. For MT we use a 2-D frequency-domain finite-element
156 code to calculate both the transverse electric (TE) and transverse magnetic
157 (TM) mode impedances for a number of frequencies (Wannamaker et al.,
158 1987).

159 2.0.3. Inversion procedure

160 A Hessian-free Gauss-Newton minimization method (Nocedal and Wright,
161 2006), which has a rapid quadratic convergence as long as the local behavior

162 is not strongly non-linear, is used to iteratively solve the linearized inver-
 163 sion problems. To solve the associated linear system, the LSQR solver from
 164 Paige and Saunders (1982) is employed. We use first-arrival times of all
 165 shot-receiver combinations as seismic data ($\mathbf{d}^{seis.}$), the z-component of the
 166 gravity field at all measuring locations as gravity data ($\mathbf{d}^{grav.}$) and real and
 167 imaginary part of the impedances for a number of frequencies and at all MT
 168 stations as MT data (\mathbf{d}^{MT}). Model parameters are seismic velocities $\mathbf{m}^{vel.}$,
 169 densities $\mathbf{m}^{dens.}$ and logarithmic values of resistivities $\mathbf{m}^{res.}$ of the inversion
 170 cells. Smoothing constraints based on Laplacian differences (Ammon and
 171 Vidale, 1993) are employed as regularization to stabilize the inversion. The
 172 inversion step lengths are adjusted at every iteration through a line search
 173 procedure (Moré and Thunent, 1994).

174 Unlike most other joint inversion schemes, the inversion processes of the
 175 individual methods are performed separately from each other. The required
 176 coupling between the individual inversions is provided by an additional con-
 177 straint in the objective function for each inversion accounting for relation-
 178 ships between the three model parameters $\mathbf{m}^{res.}$, $\mathbf{m}^{vel.}$ and $\mathbf{m}^{dens.}$. We choose
 179 this approach since it avoids the necessity to find an adequate scaling be-
 180 tween terms related to different methods in a combined objective function
 181 (i.e. Moorkamp et al., 2011). However, synchronization between the individ-
 182 ual processes is required to treat all methods equally. This is achieved by
 183 performing a single inversion step for all three methods and updating the
 184 associated coupling constraints before the next iteration is started.

185 For our joint inversion method the objective functions for the MT, seismic

186 and gravity inversion Φ^{MT} , $\Phi^{seis.}$ and $\Phi^{grav.}$ are:

$$\begin{aligned}
\Phi^{MT} &= \Phi_{(d)}^{MT}(\mathbf{m}^{res.}) + (\lambda^{MT})^2 \Phi_{(m)}^{MT}(\mathbf{m}^{res.}) + (\mu^{MT})^2 \Phi_{(c)}^{MT}(\mathbf{m}^{res.}, \tilde{\mathbf{m}}^{res.}) \longrightarrow min \\
\Phi^{seis.} &= \Phi_{(d)}^{seis.}(\mathbf{m}^{vel.}) + (\lambda^{seis.})^2 \Phi_{(m)}^{seis.}(\mathbf{m}^{vel.}) + (\mu^{seis.})^2 \Phi_{(c)}^{seis.}(\mathbf{m}^{vel.}, \tilde{\mathbf{m}}^{vel.}) \longrightarrow min \\
\Phi^{grav.} &= \Phi_{(d)}^{grav.}(\mathbf{m}^{dens.}) + (\lambda^{grav.})^2 \Phi_{(m)}^{grav.}(\mathbf{m}^{dens.}) + (\mu^{grav.})^2 \Phi_{(c)}^{grav.}(\mathbf{m}^{dens.}, \tilde{\mathbf{m}}^{dens.}) \longrightarrow min
\end{aligned}$$

187 where $\Phi_{(d)} = [\mathbf{g}(\mathbf{m}) - \mathbf{d}_{obs.}]^T \mathbf{D}^T \mathbf{D} [\mathbf{g}(\mathbf{m}) - \mathbf{d}_{obs.}]$ are the data terms, $\Phi_{(m)} =$
188 $\mathbf{m}^T \mathbf{C}^T \mathbf{C} \mathbf{m}$ are the regularization terms, $\Phi_{(c)}$ are the terms that account
189 for the parameter relationships, $\mathbf{d}_{obs.}$ is the vector containing the observed
190 data, $\mathbf{g}(\mathbf{m})$ is the vector containing the calculated data obtained by forward
191 modeling, $\mathbf{D}^T \mathbf{D} = \mathbf{C}_{(d)}^{-1}$ is the inverse of the data covariance matrix and
192 \mathbf{C} is the roughness matrix (containing discrete first-order derivatives). The
193 impact of the individual terms is governed by the regularization and coupling
194 parameters λ^{MT} , $\lambda^{seis.}$, $\lambda^{grav.}$ and μ^{MT} , $\mu^{seis.}$, $\mu^{grav.}$, respectively.

195 While the data terms $\Phi_{(d)}$ and regularization terms $\Phi_{(m)}$ are commonly
196 used in all types of inversions, the coupling terms $\Phi_{(c)}$ are **particular** to joint
197 inversion. $\Phi_{(c)}$ express the coupling between the individual inversions as
198 minimization problems ($\Phi_{(c)} \longrightarrow min$) and describe, in our case, how far
199 the model parameters $\mathbf{m}^{res.}$, $\mathbf{m}^{vel.}$ and $\mathbf{m}^{dens.}$ deviate from the proposed rock
200 parameter relationships. To determine the constraints of the $\Phi_{(c)}$ for all N
201 inversion cells, projections $\tilde{\mathbf{m}}$ onto the pre-defined relationship curve are cal-
202 culated from the physical parameters \mathbf{m} . The distances between the model
203 parameters \mathbf{m} and their projections $\tilde{\mathbf{m}}$ are then used to define the minimiza-

tion problems for $\Phi_{(c)}$ as:

$$\begin{aligned}\Phi_{(c)}^{MT}(\mathbf{m}^{res.}, \tilde{\mathbf{m}}^{res.}(\mathbf{m}^{res.}, \mathbf{m}^{vel.}, \mathbf{m}^{dens.})) &= \sum_{j=1}^N (m_j^{res.} - \tilde{m}_j^{res.}(m^{res.}, m^{vel.}, m^{dens.}))^2 \\ \Phi_{(c)}^{seis.}(\mathbf{m}^{vel.}, \tilde{\mathbf{m}}^{vel.}(\mathbf{m}^{res.}, \mathbf{m}^{vel.}, \mathbf{m}^{dens.})) &= \sum_{j=1}^N (m_j^{vel.} - \tilde{m}_j^{vel.}(m^{res.}, m^{vel.}, m^{dens.}))^2 \\ \Phi_{(c)}^{grav.}(\mathbf{m}^{dens.}, \tilde{\mathbf{m}}^{dens.}(\mathbf{m}^{res.}, \mathbf{m}^{vel.}, \mathbf{m}^{dens.})) &= \sum_{j=1}^N (m_j^{dens.} - \tilde{m}_j^{dens.}(m^{res.}, m^{vel.}, m^{dens.}))^2\end{aligned}$$

(Note that the all three $\Phi_{(c)}$ terms are dependent on all three physical parameters.)

Practical meaning of this implementation is that associated constraints pull the model parameters $\mathbf{m}^{res.}$, $\mathbf{m}^{vel.}$ and $\mathbf{m}^{dens.}$ towards the relationship curves such that the relative behaviour of the different physical models is approximately described by the parameter relationships.

The projection method proposed here (see Appendix A for a detailed description) has the advantage that the impact of all physical parameters is equally balanced independent of their parameter ranges. However, it is only applicable for parameter relationships that have a strictly monotonic behaviour.

2.0.4. Adjust the projection by using model resolution estimates

Another advantage of the way the projection is implemented is the possibility to take into account the resolving power of different methods at each individual cell. In the Appendix B we describe how the projection presented in Appendix A is modified such that it has the following behaviour: if method 1 (e.g. seismic) has a high resolution and the other methods (e.g. MT and gravity) have low resolutions in an inversion cell, the resulting parameters

223 from the projection are very similar to the one obtained from the method
 224 1 e.g. velocity of the projection is very similar to the velocity of the seis-
 225 mic model and resistivity (density) of the projection are very similar to the
 226 resistivity (density) calculated from the seismic velocity model by means of
 227 the parameter relationships (see also black dot in Fig. A.18b in Appendix
 228 A). If the resolution powers of the different methods are in a similar range,
 229 the parameters from the projections are averages which are similarly affected
 230 by all model parameters. Such implementation improves the performance of
 231 the joint inversion and reduces the number of required iterations to reach
 232 an adequate data misfit, because the projection direction is guided spatially
 233 flexible by the relative impact of the different data sets.

234 A good measure for evaluating the resolution of a method is the diago-
 235 nal of the model resolution matrix $\mathbf{R} = ((\mathbf{G}^T \mathbf{G} + \lambda^2 \mathbf{C}^T \mathbf{C})^{-1} \mathbf{G}^T) \mathbf{G}$ (where
 236 $\mathbf{G} = \mathbf{D}\mathbf{S}$ and \mathbf{S} is the sensitivity matrix). \mathbf{R} is normalized to 1.0 and 0.0,
 237 where 1.0 indicates perfectly and 0.0 not resolved at all parameters, respec-
 238 tively. Retrieving the diagonal by calculating the complete resolution ma-
 239 trix, however, is difficult for large inverse problems since it requires computer
 240 memory of the size $N \times N$. We therefore use instead an efficient stochas-
 241 tic estimation of the resolution matrix diagonal suggested by MacCarthy
 242 et al. (2011). They arrange the equation for the model resolution matrix
 243 such that its diagonal can be solved with the same linear system as used for
 244 the corresponding linearized inversion problem (see equations 7 to 9 in their
 245 publication). (As in their equation 9 we consider the regularization terms
 246 in the calculation of the resolution matrix diagonal; however, we ignore the
 247 coupling terms.) Their approach is based on the work from Bekas et al.

(2007), who developed a statistical procedure to determine the diagonal of a large $P \times P$ matrix by iteratively applying a sequence of P -length random vectors to this matrix. Although the quality of the diagonal estimates depends onto the number of iterations, we restrict them to maximum 5000 in our runs to keep computation times low. If the diagonal elements are assigned to the associated inversion cells, the obtained models showing the resolution estimates appears slightly noisy. To remove this noise and smooth the resolutions estimates in the spatial directions, the median of resolution parameters is determined from all neighbouring cells for each cell and applied as the final resolution measures in the parameter projection.

2.0.5. Adaptive determination of the coupling parameters

In our experience it is necessary need to keep the coupling parameters μ flexible during the inversion process. This can be explained as follows. Each method has its natural convergence path through the model space to decrease its data misfit. These paths may differ substantially for the different methods (e.g. MT and seismic tomography are strongly non-linear methods, whereas gravity is a linear method). Since the projection on the parameter relationship curve depends on the model parameters of all three methods, **it is possible that, during the inversion process, the natural** convergence direction for some of the methods points in a completely different direction in the model space to that the associated coupling constraint points. This can even occur when the parameter relationships perfectly describe the rock property behaviour. If the weight of the coupling parameter μ is chosen too high, the associated constraints force the parameter models in wrong directions, the convergence of the inversion is slowed down and the individual inversion

may then get trapped in local minima where the data misfit is not properly minimized. In contrast, coupling strengths which are too weak may lead to parameter models which are barely linked and, hence, the potential of increasing the resolution through joint inversion is then not utilized.

To avoid such scenarios we implement a scheme to vary the coupling parameters μ^{MT} , $\mu^{seis.}$ and $\mu^{grav.}$ for the individual methods adaptively and independently from each other during the inversion process. The adaption of the coupling parameters is implemented in exactly the same way for all three methods and we thus explain the procedure here for one method only.

The adaptation criterion is based on the idea that the coupling constraint should affect the convergence behaviour of the objective function at each iteration, k , by the same amount. It states that the incremental change of the sum of the data and regularization terms of the objective function

$$\Delta\Phi_{(d+m)}^{Constr.,k} := (\Phi_{(d)}^{Constr.,k} + \lambda^2\Phi_{(m)}^{Constr.,k}) - (\Phi_{(d)}^{Constr.,k-1} + \lambda^2\Phi_{(m)}^{Constr.,k-1}) \quad (1)$$

for our constrained inversion should correspond to a specified portion D (with $1.0 > D > 0.0$) of the same terms

$$\Delta\Phi_{(d+m)}^{Ref.,k} := (\Phi_{(d)}^{Ref.,k} + \lambda^2\Phi_{(m)}^{Ref.,k}) - (\Phi_{(d)}^{Constr.,k-1} + \lambda^2\Phi_{(m)}^{Constr.,k-1}) \quad (2)$$

for a reference inversion without constraint ($\mu_k = 0$):

$$\Delta\Phi_{(d+m)}^{Constr.,k} = D\Delta\Phi_{(d+m)}^{Ref.,k} \quad (3)$$

The meaning of the criterion is illustrated in Figure 1.

Figure 1: Sketch illustrating the adaption criterion for the coupling parameters at iteration. The parameter μ is chosen such that the change of data term plus regularization term of the objective function $\Delta\Phi_{(d+m)}^{Constr.,k}$ of the constrained inversion at iteration k (black line) is a predetermined factor D smaller than for the change of these terms $\Delta\Phi_{(d+m)}^{Ref.,k}$ for the unconstrained inversion (red line).

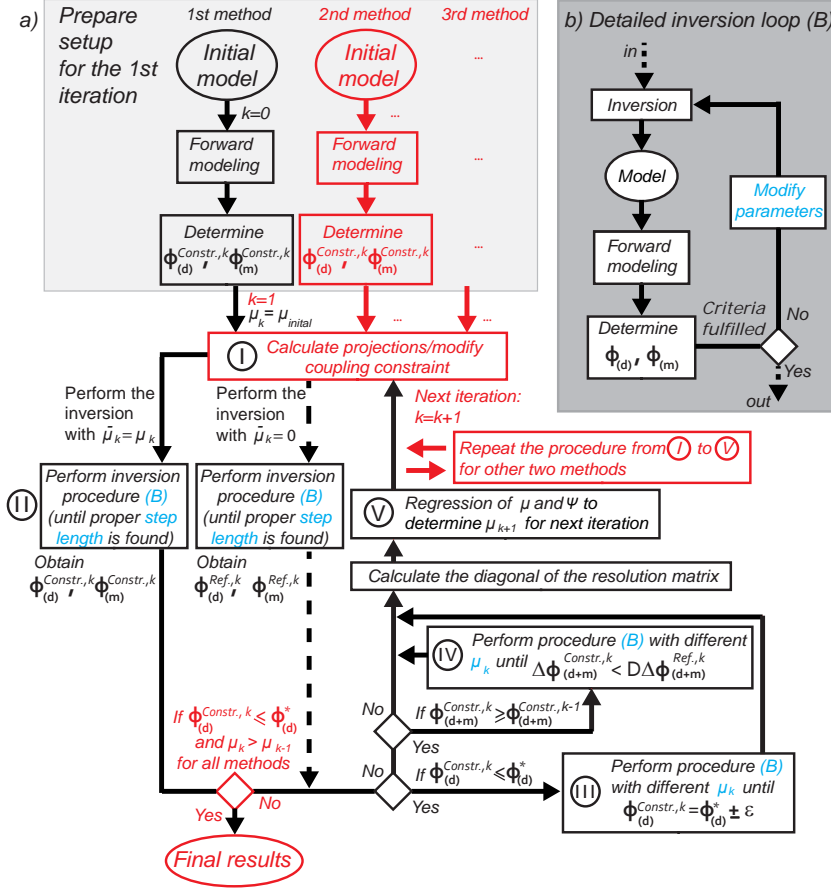

Figure 2: a) Flowchart illustrating the adaptive inversion scheme. The scheme shows the procedure for only one of the methods. For the other methods the procedure is equivalent. Steps where information from the other methods are involved are highlighted in red colors. Roman numerals mark the different steps that are explained in the body of the text. The grey box b) shows an inversion loop, which is performed at different stages of the procedure (see blue letters (B) in a)) and in which the fulfillment of different criteria are tested: At stage II the step length is varied until the Wolfe conditions (Nocedal and Wright, 2006) are satisfied and at stages III and IV μ_k is varied until criteria are reached that consider the behavior of the objective functions.

290 Although this criterion specifies how the terms $\Delta\Phi_{(d+m)}^{Constr.}$ of our con-
 291 strained inversion should change at each iteration step, it does not explicitly
 292 depend on μ . This means that an additional assumption linking the vari-
 293 ations of $\Delta\Phi_{(d+m)}$ with the ones of the μ values is required to be able to
 294 develop an adaptive scheme. Here, we assume that μ is approximately linear
 295 with the normalized incremental change of the objective function Ψ_l for a
 296 number of L successive iterations:

$$\mu_l \approx p_k^{(0)} + p_k^{(1)} \underbrace{\frac{\Delta\Phi_{(d+m)}^{Ref.,l} - \Delta\Phi_{(d+m)}^{Constr.,l}}{\Delta\Phi_{(d+m)}^{Ref.,l}}}_{=:\Psi_l} \quad \text{with } l = k - (L - 1), \dots, k \quad (4)$$

297 To update μ at every iteration the criterion and the assumption (eq. 4) are
 298 combined in the scheme shown in Figure 2.

299 For iteration k :

- 300 1. the coupling constraint associated with the parameter relationship is
 301 determined (see ① in Fig. 2)
- 302 2. two model updates (inversion steps) - one with and one without the
 303 coupling constraint - are performed (see ② and panel (B) in Fig. 2).
- 304 3. forward calculations are conducted for both updated models and the
 305 associated terms of the objective functions $\Phi_{(d+m)}^{Constr.,k}$ and $\Phi_{(d+m)}^{Ref.,k}$ are
 306 determined. Steps 2 and 3 are repeated with different inversion step
 307 lengths as long as the step length criteria (Moré and Thunente, 1994)
 308 are not satisfied (see ③ and box (B) in Fig. 2).
- 309 4. the diagonal of the resolution matrix is calculated to adjust the projec-
 310 tion.

311 5. a linear regression of normalized incremental change of the objective
 312 functions $\Psi_{\tilde{l}}$ and coupling parameters $\mu_{\tilde{l}}$ from a number of previous
 313 iterations $\tilde{l} = k - (\tilde{L} - 1), \dots, k$ is carried out (see \odot in Fig. 2). The
 314 axis intercept $p_k^{(0)}$ and slope $p_k^{(1)}$ from the linear regression are then
 315 used to calculate the coupling parameter μ_{k+1} for the next iteration by
 316 means of the formula

$$\mu_{k+1} = (1 - D)p_k^{(1)} + p_k^{(0)} \quad , \quad (5)$$

317 which is obtained by a combination of eq. 3 and eq. 4.

318 6. Steps 1) to 5) are repeated for the other two methods.

319 Steps 1) to 6) are repeated at each iteration.

320 The convergence speed is controlled by the parameter D and the number
 321 of previous iterations \tilde{L} , from which information is used in the regression. For
 322 larger values of D it is assumed that the data misfit for the corresponding
 323 method decreases generally faster during the inversion process (see eq. 3) and
 324 that the resulting μ are smaller (see eq. 5). This means that the associated
 325 method is less coupled. For larger values of \tilde{L} the adaptive algorithm reacts
 326 more inertly if the effect of the relationship constraint onto the convergence
 327 behaviour changes. On the other hand, regression becomes less sensitive to
 328 outliers and, hence, the algorithm can be considered as more robust.

329 Regression results and consequently updates of μ only depend on the
 330 distribution of $\mu_{\tilde{l}}$ and $\Phi_{\tilde{l}}$ from a small number of previous iterations (typically
 331 < 6), therefore updated μ 's are only local and not global estimates of the
 332 best suited values for the coupling at the corresponding iteration. However,
 333 we tested our scheme on different synthetic examples and observe that the

implemented adjustment of coupling parameters is in most cases sufficient to obtain stable convergence behaviour for individual inversions. The same tests lead us to conclude that D should be in the range of 0.4 - 0.9 and \tilde{L} should be in the range of 2 - 5 to ensure robust and fast convergence.

Nonetheless, under some circumstances the assumption of eq. 4 may not be appropriate for a specific method and iteration and the determined update of μ results in an increase of the remaining objective function $\Phi_{(d+m)}^{Constr.,k} \geq \Phi_{(d+m)}^{Constr.,k-1}$. To guarantee convergence, the value of μ_k is then recalculated in such cases: The inversion loop is repeated for different μ -values (see box (B) and (iv) in Fig. 2) and by means of interpolation (bisection method) an appropriate coupling parameter is found which satisfies the condition $\Delta\Phi_{(d+m)}^{Constr.,k} < D\Delta\Phi_{(d+m)}^{Ref.,k}$. We emphasize that the procedure to recalculate μ is often significantly more time-consuming than determining μ by adaption, because more forward calculations are required (typically a factor 2-4). Even if μ values determined from the adaptive procedure provide model updates that only roughly satisfy the criterion, it is more useful to take information from previous iterations to avoid slowing down the joint inversion process.

When the data term of the objective function gets smaller than the specified target misfit $\Phi_{(d)}^{Constr.} \leq \Phi_{(d)}^*$ (typically associated with an error weighted data misfit close to 1.0), in principal a solution is found for the associated method. Modification of the associated μ by the adaptive algorithm is then no longer required and one option would be to keep μ unchanged in the following iterations. However, since we are interested in finding the solution with the strongest possible coupling, we want to identify instead the largest μ that is compatible with the data. For this purpose, we choose a similar

359 procedure as proposed by Constable et al. (1987) and de Groot-Hedlin and
 360 Constable (1990), who searches for the smoothest model that explains the
 361 data (Occam’s inversion). However, in contrast to their approach we consider
 362 μ^{-1} (and not λ^{-1}) as the Lagrangian multiplier that is adjusted when $\Phi_{(d)}^*$ is
 363 reached for the associated method. The inversion loop is therefore repeated
 364 for a number of different μ and an interpolation method is employed (bisec-
 365 tion method) to find the coupling parameter with the largest value which
 366 satisfies $\Phi_{(d)}^* - \epsilon \leq \Phi_{(d)}^{Constr.} \leq \Phi_{(d)}^* + \epsilon$ (with ϵ being a small positive quantity)
 367 for the next iteration (see box (B) and $\textcircled{\text{III}}$ in Fig. 2).

368 The complete inversion procedure stops, when all methods reach their
 369 specified target misfits and no increase in the coupling parameters can be
 370 achieved in the next iteration.

371 *2.0.6. Adjustment of smoothing parameter*

372 We have tested different methods to adjust the smoothing during the
 373 inversion process (including the adaptive scheme used to modify μ). They
 374 show that the convergence behavior is less influenced by the regularisation
 375 than by the coupling parameters. Several of the conventional techniques to
 376 modify λ demonstrate that they are well suited to reach the target misfits and
 377 we use a simple technique with a cooling-schedule-type behaviour proposed
 378 by Lelièvre et al. (2012). An initially large value for λ is chosen that is
 379 reduced with increasing number of iterations. In this way progressively more
 380 detailed structures are introduced into the models. The factor of reduction
 381 $1/\nu_k$ from one iteration to the next:

$$\frac{1}{\nu_k} = \frac{\lambda_{k+1}}{\lambda_k} \tag{6}$$

382 is determined by

$$\begin{aligned}\nu_k &= 1 + \tau \left| \Phi_{(d)}^k / \Phi_{(d)}^* - 1 \right| & \text{if } \Phi_{(d)}^k > \Phi_{(d)}^* \\ \nu_k &= 1 & \text{if } \Phi_{(d)}^k \leq \Phi_{(d)}^*.\end{aligned}$$

383 Typical values used for the parameter τ are in the range of 0.02 - 0.2. The
384 rate of reduction depends on the actual target misfit $\Phi_{(d)}^*$ and ν_k remains
385 constant if the target misfit is reached. To avoid overly fast reduction of the
386 regularization, ν is limited to values between 1 and 2. If a regularization
387 parameter becomes smaller than a specific threshold value λ^* , the procedure
388 stops and the regularization remains unchanged ($\lambda = \lambda^*$) for further itera-
389 tions to avoid instabilities in the inversions. Values for λ^* used in this study
390 range from 0.7 to 1.0 depending on the methods.

391 *2.0.7. Implementation of structural cross-coupling*

392 The adaptive method can be extended to include structural information
393 at the same time. We have implemented an approach suggested by Günther
394 and Rücker (2006), where cross-coupling is achieved through mutually con-
395 trolling smoothing constraints of a given parameter model by the roughness
396 distribution from other parameter models. Thus a strong spatial parameter
397 contrast existing in at least one of the parameter models can be transferred
398 to the other parameter models.

399 This cross-coupling scheme is implemented as follows. Firstly, at the k -th
400 iteration the roughness vectors \mathbf{r} are calculated for all models using:

$$\begin{aligned}
\mathbf{r}^{res.} &= \mathbf{C}\mathbf{m}^{res.} \\
\mathbf{r}^{vel.} &= \mathbf{C}\mathbf{m}^{vel.} \\
\mathbf{r}^{dens.} &= \mathbf{C}\mathbf{m}^{dens.}
\end{aligned}$$

401 where $\mathbf{C} \in \mathbb{R}^{B \times N}$ is the roughness matrix (where B is the number of cell
 402 boundaries and N the number of inversion cells). Secondly, weights w_1, \dots, w_B
 403 are determined for each method by means of the associated roughness vectors:

$$w_j = \min(h_j, 1.0) \quad \text{with} \quad h_j = \left(\frac{\alpha}{\frac{|r_j|}{\|\mathbf{r}\|} + \alpha} + \alpha \right)^\beta \quad (7)$$

where the constants α and β have typical values of 0.1 and 1.0.

404 Finally, the weights for the model of one method are used to modify the
 405 regularisation terms for the other models:

$$\begin{aligned}
\Phi_{(m)}^{MT} &= \left\| \sqrt{\mathbf{W}^{vel.} \mathbf{W}^{dens.}} \mathbf{C}\mathbf{m}^{res.} \right\|_2^2 \\
\Phi_{(m)}^{seis.} &= \left\| \sqrt{\mathbf{W}^{res.} \mathbf{W}^{dens.}} \mathbf{C}\mathbf{m}^{vel.} \right\|_2^2 \\
\Phi_{(m)}^{grav.} &= \left\| \sqrt{\mathbf{W}^{res.} \mathbf{W}^{vel.}} \mathbf{C}\mathbf{m}^{dens.} \right\|_2^2
\end{aligned}$$

with $\mathbf{W} = \text{diag}(w_1, \dots, w_B)$ (weighting matrix)

406 The procedure of this structural cross-coupling strategy is illustrated for
 407 one iteration and two methods in Figure 3. In our inversion scheme the
 408 structural-cross coupling is performed immediately at the beginning of each
 409 iteration (before the coupling constraints for the petrophysical relationships
 410 are calculated; see ① in flowchart in Fig. 2).

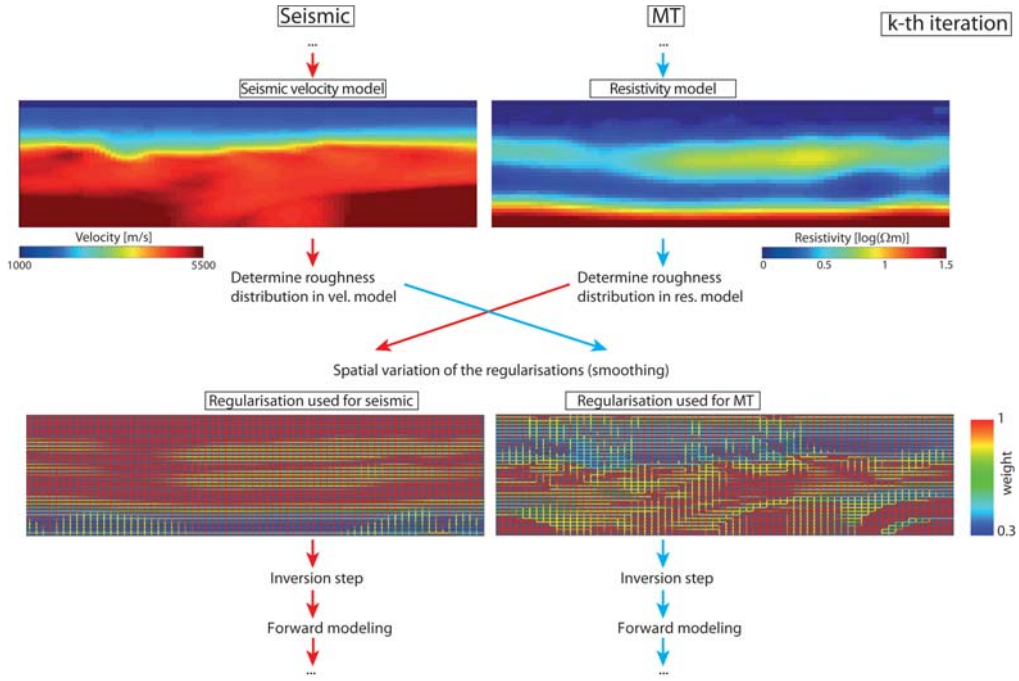

Figure 3: Sketch illustrating the structural cross-coupling strategy proposed by Günther and Rücker (2006). In the upper panel we show a velocity and resistivity model derived at the k -th iteration for the inversion of seismic tomography and MT data for a synthetic sub-basalt model (see next section for a more detailed discussion). The roughnesses of one model is used to calculate the weights for the smoothing constraints of the other model (see bottom panels); and vice versa.

411 3. SYNTHETIC TEST ON A SUB-BASALT MODEL

412 We test our adaptive inversion scheme on a 2-D synthetic basalt model.
413 The model was proposed by Martini et al. (2005) to simulate realistic seismic
414 and non-seismic data and to develop strategies for geophysical data integra-
415 tion for sub-basalt problems. It is known that imaging of sub-basalt sed-
416 iments with reflection seismic techniques is complicated due to absorption,
417 scattering and transmission effects and the presence of peg-leg multiples (e.g.
418 Purnell, 1992). Although many of the difficulties facing conventional seismic
419 profiles can be overcome by recording long offset data (e.g. Fliedner and
420 White, 2003), resolution of sub-basalt structures in seismic sections is still
421 largely limited. Therefore multi-parametric approaches (Hautot et al., 2007;
422 Panzner et al., 2014; Hoversten et al., 2015) and joint inversion strategies
423 (Heincke et al., 2006; Colombo et al., 2008; Manglik et al., 2009; Jegen et al.,
424 2009) have been developed to gain additional information from sub-basalt
425 structures. Our simplified model contains two mostly horizontal layers that
426 have high velocity, resistivity and density (Fig. 4, upper panels). The up-
427 per layer is associated with a sequence of basalt flows and the lower layer is
428 considered to be basement. Above the basalt and between the basalt and
429 the basement there are layers with lower physical property values, which rep-
430 resent sediments over and under the basalt layer, respectively. Everywhere
431 in the synthetic model the three physical parameters resistivities ρ (in Ωm),
432 velocities v_p (in m/s) and densities d (in g/cm^3) are linked by the density-
433 velocity and resistivity-velocity relationships

$$d = 0.0002 v_p + 1.7 \quad (8a)$$

and

$$\begin{aligned} \log_{10}(\rho) &= 1.20 \log_{10}(v_p) - 3.86 & \text{for } v_p < 3600 \\ \log_{10}(\rho) &= 6.46 \log_{10}(v_p) - 22.57 & \text{for } v_p > 3600 \end{aligned} \quad (8b)$$

that are derived from commercial and ODP borehole data collected on the north west European margin (Jegen et al., 2009). At the top of the model a 400 m thick layer is added representing seawater. Physical properties of the water layer remain unchanged during the inversion ($\rho = 0.3 \text{ } \Omega\text{m}$, $v_p = 1560 \text{ m/s}$, $d = 1.0 \text{ g/cm}^3$). The model is discretized for inversion into 85×71 cells with sizes of $400 \times 100 \text{ m}$ in the horizontal and vertical directions, respectively.

The seismic and gravity data sets for the synthetic tests are generated using the same forward modeling routines as in the joint inversion. However, to reduce the impact of modelling effects that are associated with using the same forward codes, discretisations of the model for data generation are significantly finer than the ones used in the forward modeling routines during inversion. For MT we employ a different modelling program (2-D MT code from Tarits, 1984) to calculate the impedance estimates from the synthetic model to the one (2-D MT code from Wannamaker et al., 1987) we use in the joint inversion.

For seismics we consider an OBS data set with 6018 first arrivals from 177 shot and 34 receiver positions, respectively. Both shot positions at the surface and receivers at the seafloor are equally spaced ($\Delta x_{\text{shots}} = 200 \text{ m}$ and $\Delta x_{\text{receivers}} = 1000 \text{ m}$). The gravity data set is composed of 60 stations

453 located on the sea surface ($\Delta x_{\text{grav. station}} = 500 \text{ m}$). The MT data set consists
 454 of 33 stations that are equally spaced along the seafloor ($\Delta x_{\text{MT station}} = 1000$
 455 m). Such short station intervals are still uncommon for MT field surveys.
 456 However, the objective of this exercise is to evaluate the general performance
 457 of our joint inversion scheme and at this stage we prefer to use models, where
 458 the individual methods show a dense and uniform coverage. We use as input
 459 for the inversions both TE and TM mode data with 15 frequencies over a
 460 range of $2.5 \cdot 10^{-5}$ to 1 Hz. Gaussian noise is added to all data sets with
 461 standard deviations $\sigma_{\text{seis.}} = 10 \text{ ms}$, $\sigma_{\text{grav.}} = 0.05 \text{ mgal}$ and $\sigma_{\text{MT}} = 2\%$ of the
 462 abs. values, respectively.

463 To obtain a qualitative understanding about the resolution power of the
 464 individual methods we plot estimates of the diagonal elements of the reso-
 465 lution matrix (Fig. 4, lower panels) for the synthetic model. Based on this
 466 measure, seismic rays from first arrivals only provide information about the
 467 top of basalt and the overlying sediments. Resolution of gravity data varies
 468 smoothly and decreases with depth, as is typical for potential field methods.
 469 MT is sensitive to the conductive sediments, but not to the highly resistive
 470 basalt layer and basement. At the left and right border high resolution values
 471 in the (gravity and) MT are related to a background layer model required
 472 for both methods (gravity: semi-infinite horizontal sheets; MT: cells at the
 473 border, whose size increasing with the distance from the model boundary).
 474 The resolution estimate shows that all three methods are sensitive to differ-
 475 ent subsets of structural elements of the model and thus contain common but
 476 also complementary information about the entire structure. It is the com-
 477plementary information content in the data sets which allows the derivation

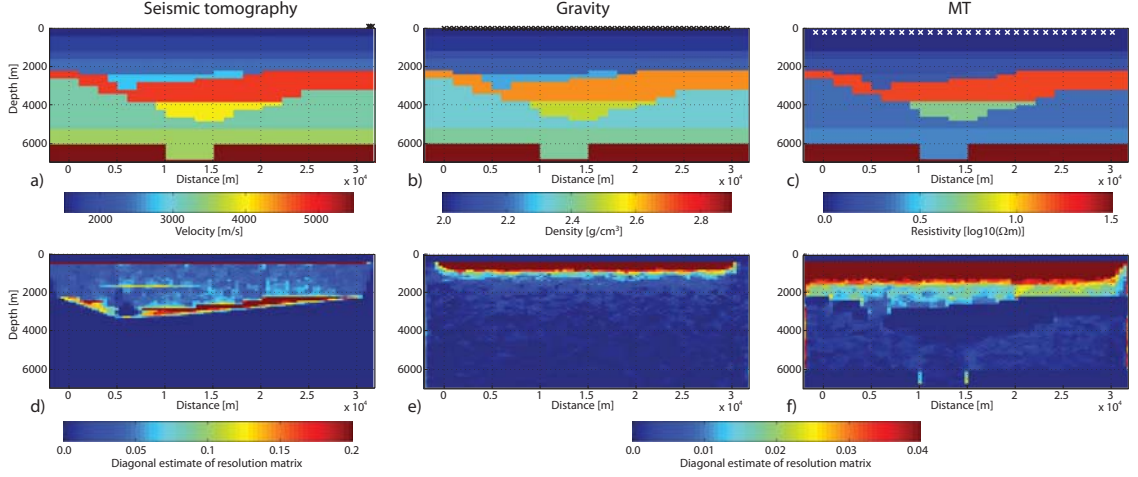

Figure 4: Upper panels: a) Velocities, b) densities and c) resistivity distributions representing the synthetic sub-basalt model. Circles denote locations of OBS stations and crosses highlight positions of shots in a), gravity stations in b) and MT stations in c). Lower panels: Approximations of the diagonal elements of the resolution matrices for each method (see section 2.0.4 for further details about their calculation). High values of resolution are found at the very right and left border of the gravity and MT data (see panels e,f) due to necessity to include a background gravity and MT model.

of an improved model through a joint inversion process.

3.1. Results from the individual inversions

Before presenting the results of the joint inversion we show results of inverting each of the datasets separately. For seismic inversion we use a starting model that consists of horizontal velocity layers, but for gravity and MT inversions starting models are homogenous half-space models. Cell sizes are the same as in the joint inversion. In contrast to the joint inversions, a conventional Occam's type inversion is performed for the individual inversions;

486 i.e. if the target misfit is reached in the inversion procedure, λ is adjusted to
487 find the smoothest model that explains the data.

488 Results of these individual inversions (Fig. 5, Row 1) show that none of
489 the three methods is able to resolve the basalt layer, the underlying sediments
490 and the basement at the same time, which confirms our prediction based on
491 the resolution analysis. Refraction seismic tomography only resolves the ve-
492 locity distribution down to the top of basalt. The gravity inversion does not
493 resolve any structure. The MT inversion identifies high and low resistive
494 structures that can be associated with the basement and conductive sedi-
495 ments, respectively, however the resistive basalt layer is not well resolved
496 (too low resistivities and inaccurate shape).

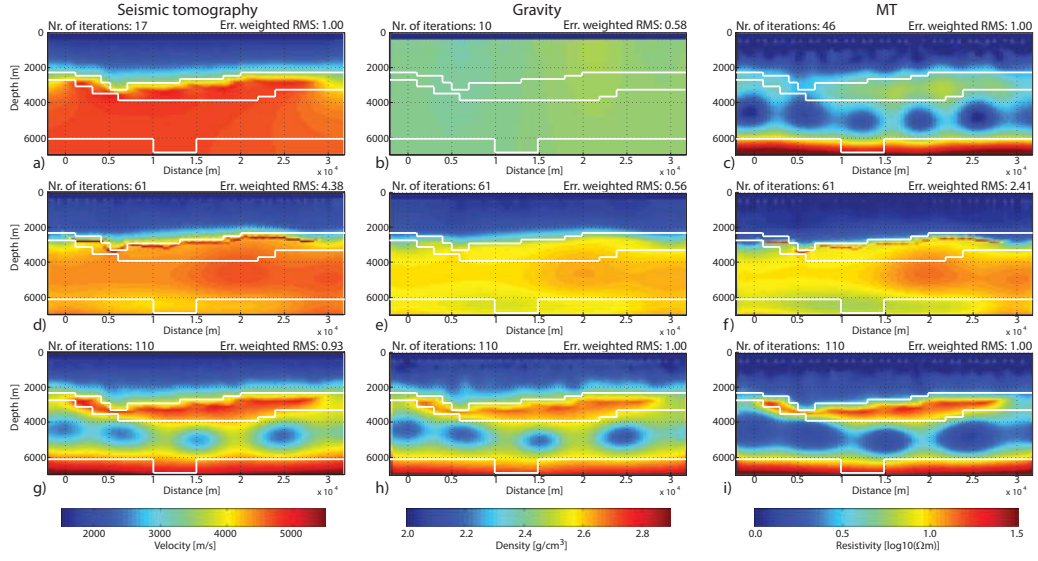

Figure 5: First row: Final results from individual Occam seismic, gravity and MT inversions. Second row: Final results from a petrophysical joint inversion, in which the strengths of coupling is kept constant ($\mu^{MT} = \mu^{seis.} = \mu^{grav.} = 0.25$) during the inversion process. Third row: Final results from a petrophysical joint inversion, in which the coupling constraints are adapted at each inversion step (rate of adaption $D^{MT} = D^{seis.} = D^{grav.}$ is 0.7 and 3 previous iterations \tilde{L} are considered in the regression). Unlike in the tests presented in Fig. 6 the projection is not modified by a resolution measure. Locations of the basalt layer and the basement are outlined with white lines.

497 3.2. Starting models for the joint inversions

498 To determine the starting models for the joint inversions, first, individual
499 seismic tomography inversion is performed. We then use the parameter rela-
500 tionship (eq. 8a) to transfer the initial velocity model to a density model. For
501 this model an individual gravity inversion is performed. During this gravity
502 inversion, density values of cells covered by seismic rays are kept fixed. Model
503 densities from the inversion results are finally transferred back to velocities
504 and also resistivities (eqs. 8a and 8b). This procedure determines starting
505 models that are already relatively close the actual subsurface; a strategy
506 commonly used in joint inversion applications. We demonstrate later in this
507 section that we obtain similarly good final joint inversion results by using
508 starting models that are not linked to each other and are further away from
509 the true model.

510 3.3. Results from petrophysically linked joint inversions

511 First, we test our joint inversion scheme with coupling parameters that
512 remain constant during the inversion process ($\mu^{seis.} = \mu^{grav.} = \mu^{MT} = 0.25$).
513 All methods are equally weighted for projections onto the parameter rela-
514 tionships, which means the resolution of each of the methods is not taken
515 into account. We also do not include structural cross coupling, however, we
516 gradually reduce the smoothing parameters (from starting values of $\lambda^{seis.} =$
517 $\lambda^{grav.} = \lambda^{MT} = 0.25$) as described in the section 2.0.6. The final results for
518 this test are not satisfying (Fig. 5, Row 2); the shape of high velocity, resis-
519 tivity and density anomalies does not coincide with the shape of the basalt
520 in our synthetic model and there are no low velocity, resistivity nor density
521 anomalies can be associated with sub-basalt sediments. Error weighted data

misfits $d_{RMS} = \sqrt{\frac{1}{M} \sum_{i=0}^M \left(\frac{g(\mathbf{m})_i - d_i}{\sigma_i} \right)^2}$ do not reach the target misfit of 1.0 for seismic ($d_{RMS}^{seis.} = 4.38$) and MT ($d_{RMS}^{MT} = 2.41$), respectively. It is likely that the inversion processes get trapped in local minima relatively close to the actual starting models. (In contrast, the error weighted data misfit for the gravity $d_{RMS}^{grav.} = 0.56$ remains clearly smaller than the target misfit of 1.0, although λ is increased, when the target misfit is reached (Occam's inversion). This indicates that the amount of smoothing has little impact onto the data misfit of the gravity.)

In the next step the joint inversion is repeated using the same starting model and initial coupling values, however, now we adaptively modify our coupling parameters. D is set to relatively high values of $D^{seis.} = D^{grav.} = D^{MT} = 0.7$ to control the convergence rate. The number of previous iterations \tilde{L} used to predict the μ -value for the next iteration is 3 for all methods. Otherwise, the starting models and other settings are the same as for the previous test.

The resulting models (Fig. 5, Row 3) are now significantly closer to the synthetic model (Fig. 4, Row 1). Two high-velocity (high-density, high-resistivity) anomalies are present in the middle and the bottom of the model. Their positions (and the shape of the upper anomaly) fit well with the two layers representing the basalt and the basement. The region between the two layers has lower values of the physical properties and can be associated with the sub-basalt sediments. However, the presence of some artificial "egg-shaped" anomalies in this part of the model indicates the limits in resolution of the joint inversion. In addition, the objective functions of all three methods decrease at each individual iteration until the associated target misfit

547 is reached (Fig. 7d)) and final error weighted data fit from all three meth-
 548 ods largely match the target misfit of 1.0 indicating a proper convergence
 549 behaviour. Only few iterations (2 and 4) are required to reach the target
 550 misfits for the gravity and seismic data, respectively, however many itera-
 551 tions (101) are required for MT. To some extent this slow convergence be-
 552 haviour seems to be inherent to the synthetic model **as already** the individual
 553 MT inversion requires 45 iterations to reach the target misfit. Furthermore
 554 the criterion used in the joint inversion (i.e. $\Phi_{(d+m)}$ of the joint inversion
 555 with coupling constraint decreases only by a portion of the one of the uncon-
 556 strained inversion) reduces the convergence speed compared to the individual
 557 MT inversions and for a value of $D^{MT} = 0.7$ one would expect that about
 558 $45/0.7 \approx 64$ iterations to be needed to reach the target misfit. One reason
 559 why almost double as many iterations are needed could be that the projec-
 560 tion linking the individual physical models is far from an optimum and this
 561 slows down the overall inversion convergence.

562 In section 2.0.4 we discuss that the convergence behaviour may improve if
 563 the projection is controlled by the relative resolution power of the individual
 564 methods. Therefore we repeat the joint inversion test, but in this case the
 565 diagonal of the resolution matrix is used to weight the individual methods in
 566 the projection calculation (see section 2.0.4). Final results (compare Fig. 6,
 567 Row 1, with Fig. 5, Row 3) are very similar, however, the convergence for the
 568 MT method is 20% faster (compare Fig. 7d) and Fig. 7e)). In addition, the
 569 updates of μ^{MT} that are determined from the linear regression are now more
 570 reasonable (i.e. $\Phi_{(d+m)}^{MT, Constr.}$ decreases) for most iterations and a readjustment
 571 of μ^{MT} by using the loop ④ (see Fig. 2) is only required for 2 iterations

(Fig. 7b)). In contrast, if the resolutions estimates are not considered in the projection (Fig. 7a), μ^{MT} has to be readjusted for at approx. 30 iterations. Based on these observations (and other synthetic examples not shown here), convergence seems faster and more stable, if resolution is incorporated in the calculation of the parameter projections.

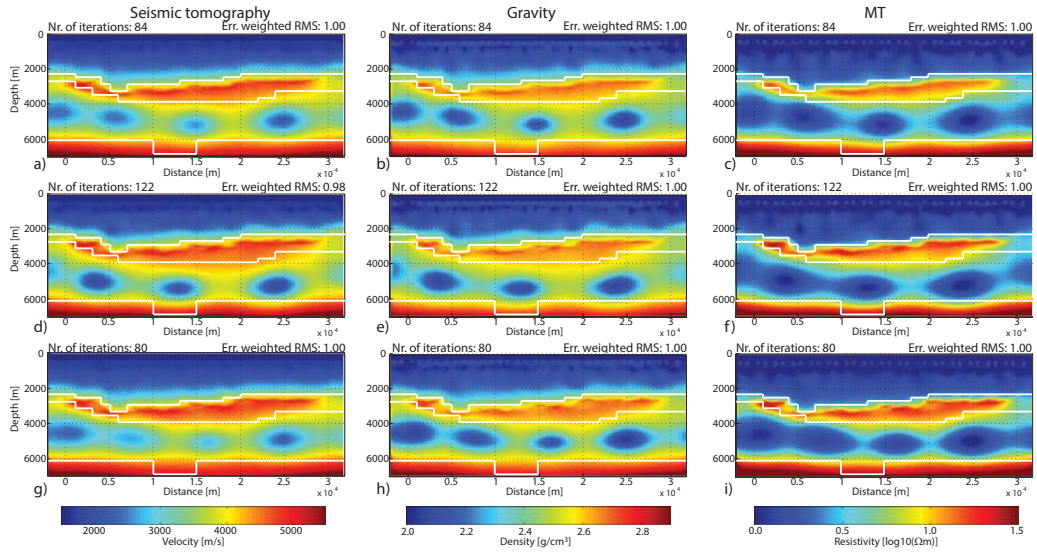

Figure 6: Final results from joint inversions, for which the strengths of coupling vary adaptively during the inversion process. For all tests shown here physical parameter projections are determined by considering relative resolution power of each method (see section 2.0.5). First and second row: Results from two tests, where different rates of adaption $D^{seis.} = D^{grav.} = D^{MT}$ of 0.7 and 0.4 are employed. Third row: Results from a test with other starting models (layered velocity model and homogenous half-space model for density $2.4g/cm^3$ and resistivity of $10\Omega m$). Otherwise the same parameters are employed as for the run, whose results are shown in the first row.

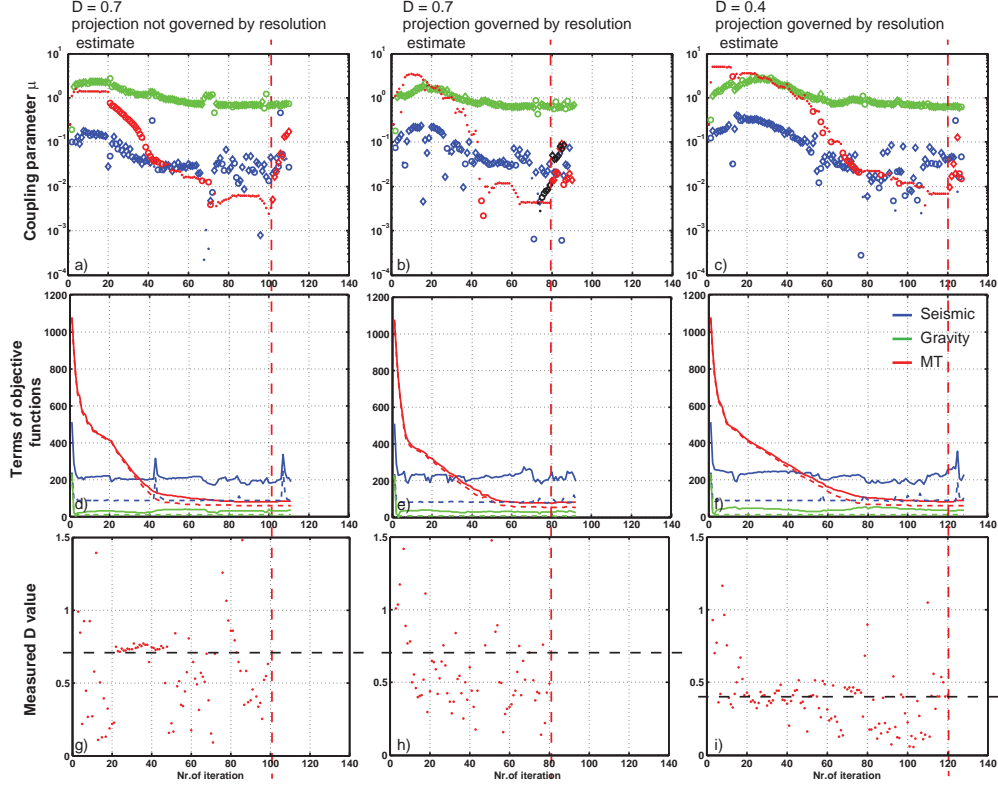

Figure 7: Behavior of the adaptive joint inversions from Figs. 5g)-i), Figs. 6a)-c) and Figs. 6d)-f) are shown in columns 1, 2 and 3, respectively. In all graphs blue refers to seismic, green to gravity and red to MT inversion parameters, shown as a function of iteration number. First row: Coupling parameters μ^{MT} , $\mu^{seis.}$ and $\mu^{grav.}$. The symbols (\diamond) and (\circ) indicate iterations, where the procedures III and IV (see Fig. 2) are active, respectively. Second row: Values of total objective functions (continuous lines) and their data terms (dashed lines). Third row: Ratio \tilde{D}^{MT} of the incremental changes of the total objective functions for inversions without and with coupling constraints. This ratio is here only shown for the MT data, because the target misfits for the other methods are reached after very few iterations (< 5). Black dashed lines mark the associated pre-defined rate of adaption D^{MT} . Vertical red dashed lines indicate the iterations for which the target misfits are reached for all three methods.

577 For all adaptive joint inversions tests presented here, the inversion run is
 578 not terminated immediately after target misfits are reached for all methods,
 579 but continued for some additional iterations. As described in section 2.0.6,
 580 this strategy is adopted from Occam’s inversion (see also loop ④ in Fig. 2).
 581 Because three parameters (μ^{MT} , $\mu^{seis.}$, $\mu^{grav.}$) are adjusted simultaneously, it
 582 is difficult to find uniquely defined stopping criteria that reliably work for all
 583 types of models, methods and data sets. We therefore stop the joint inversion
 584 manually, when one of the coupling parameters shows a significant decrease
 585 for a few subsequent **iterations**. We generally observe that the model results
 586 are slightly better (**i.e. in particular the physical properties of the basalt layer**
 587 **are higher and closer to the ones of the synthetic model**) if the procedure is
 588 not terminated immediately after all target misfits are reached.

589 3.3.1. Impact of the parameters D onto the joint inversion behaviour

590 As discussed in section 2.0.5, the parameters D have in theory a large
 591 impact on the convergence speed for the associated methods. To investigate
 592 this in more detail, the previous joint inversion test is repeated with the
 593 same settings as before except for a lower value for $D^{seis.}$, $D^{grav.}$ and D^{MT}
 594 of 0.4. Obtained final models are very similar to the ones from the previous
 595 inversion run where $D = 0.7$ is used (Rows 1 and 2 in Fig. 6). However, as
 596 expected for decreased D values we require now significantly more iterations
 597 (120 compared to 81 iterations with higher D values) to reach the given target
 598 misfit (Fig. 7e) and f)). We also observe that the coupling parameter μ^{MT}
 599 has generally slightly higher values for a lower D^{MT} than for a larger D^{MT}
 600 values (Fig. 7b) and c)). This can be explained by the general behaviour of
 601 inversions that slower convergence correlates with stronger constraints.

602 3.3.2. Validation of the linear assumption of μ and Ψ

603 The linear assumption between the coupling parameters μ and the nor-
 604 malized changes in the objective functions Ψ in eq. 4 is intuitively made.
 605 Therefore we now test if it is appropriate and evaluate its effect on the ef-
 606 ficiency of the joint inversion. The assumption can be considered as appro-
 607 priate as long as the modified μ from the regression provide a convergent
 608 behaviour (i.e. a decrease of $\Phi_{(d+m)}^{Constr.}$). For our joint inversion runs, the MT
 609 part shows a convergent behaviour for most iterations (see small red dots
 610 in the Figs. 7a)-c)). Particularly the run, where we use large D -values of
 611 0.7 and employ a resolution measure in the projection calculation, exhibits
 612 convergent behaviour for all but two iterations (see Fig. 7b and section 3.3).

613 To obtain a more quantitative measure to evaluate the validity of our
 614 assumption, we calculate for each method and for each iteration k :

$$\tilde{D} = \frac{\Delta\Phi_{(d+m)}^{Constr.,k}}{\Delta\Phi_{(d+m)}^{Ref.,k}}. \quad (9)$$

615 If the assumption is perfectly valid, \tilde{D} would equal D . For the test run
 616 with $D^{MT} = 0.4$ we obtain a similar median of the \tilde{D}^{MT} values of 0.378 and
 617 relatively low scatter of the \tilde{D}^{MT} values with a $\sigma^2 = 0.042$ (Fig. 7i)), if we
 618 only consider D -values from iterations in which μ values are not modified by
 619 loop ④. It indicates that the linear regressions provide updates of coupling
 620 parameters which seem to satisfy the assumption. For a larger D^{MT} -value of
 621 0.7, a larger discrepancy of the median value (0.508) and a larger variance
 622 of $\sigma^2 = 0.42$ suggest that the assumption is less appropriate (Fig. 7h). We
 623 have made several further tests with other D -values that confirm that a lower
 624 D -value results in a better controlled convergence behaviour.

At first glance, the better controlled convergence for low D -values appears to contradict the previous observation that convergence failed for fewer iterations when higher D -values are used. However, one has to consider that lower D -values (eq. 3) result in a slower convergence such that already a small scatter of the \tilde{D} -values can result in an increase of $\Phi_{(d+m)}^{Constr.}$ at any iteration. In summary, it is not easy to draw any general conclusions, for which D -values the assumption provides a convergent behaviour for most iterations. This is probably highly dependent on the methods involved and other settings of the actual inversion.

3.3.3. Dependence of the starting model

We repeat the joint inversion test with $D^{seis.} = D^{grav.} = D^{MT} = 0.7$ with different starting models, which are not linked by the parameter relationships and are further away from the synthetic model. Homogenous half-space models with $2.4g/cm^3$ and $10\Omega m$ are chosen for the gravity and MT inversions, respectively, and a layered velocity model is taken for the seismic inversion. Final results are similar to the ones from the joint inversion having the same parameter settings, but starting models that are linked by parameter relationships (see section 3.3) (compare the Rows 1 and 3 in Fig. 6). Convergence speed of gravity and seismic inversion is similar, but MT inversion reaches the target misfit even faster after 67 iterations compared to 81 iterations.

The choice of the starting model seems not critical for conditions, where the total resolution of the joint inversion is rather high and all models explaining the data are similar. We attribute this to the observation that adaption of the coupling strengths reduces the risk that the inversions get stuck in a local minima.

650 *3.4. Results from joint inversions using both petrophysical and structural in-*
651 *formation*

652 To further improve the results from the petrophysical inversion we now
653 add structural information. First, we test a purely structural joint inversion
654 using the mutual cross-coupling strategy described in the methodological
655 section 2.0.7. The weights applied to the discrete derivative matrix \mathbf{C} are
656 calculated using values of 0.1 and 1.0 for the parameters α and β in eq. 7,
657 respectively. As starting models the same linked parameter models are used
658 as described before.

659 This joint inversion run gets stuck in some local minima and misfits for
660 seismic (minimum $d_{RMS}^{seis.} = 4.72$) and MT (minimum $d_{RMS}^{MT} = 2.64$) and
661 do not reach the target misfits. We conclude that starting models close to
662 the synthetic models are required to such that this approach is successful.
663 And although our starting models are derived from the final results of the
664 individual inversions they are still too inaccurate to provide conditions for
665 the structural joint inversion to converge. We note that other studies using
666 this coupling strategy successfully combine geophysical methods with higher
667 resolutions (e.g. seismic tomographic and electrical resistance tomography,
668 Günther and Rücker, 2006), where the starting models obtained from indi-
669 vidual inversions are close enough to the true subsurface conditions to ensure
670 convergence of the joint inversion.

671 Based on this observation, we choose as starting models for the combined
672 structural and petrophysical joint inversion the models from the 72th itera-
673 tion of the adaptive joint inversion with $D^{seis.} = D^{grav.} = D^{MT} = 0.7$ and
674 a resolution measure in the projection calculation. In all three parameter

models locations of main anomalies are overlapping such that it can be assumed that these starting models are close enough to the synthetic model for the inversion to converge. Target misfits for all methods are reached after few iterations (< 6 for all methods). The coupling parameters are generally slightly higher than for the corresponding purely petrophysical joint inversion (see black symbols in Fig. 7b), probably due to the fact that overall smoothing is reduced by cross-coupling such that more coupling is required to obtain the same data misfits as for the inversion without structural linkage.

Final results (Fig. 8) show that this combined structural and petrophysical joint inversion resolves the main structures as well as the purely petrophysically coupled joint inversion. However, the boundary between the upper sediments and the basalt is now sharpened in all three parameter models (compare with results in Fig. 6) and its location coincides well with upper sediments-basalt interface in the synthetic model. This demonstrates that a combination of both structural and petrophysical linkage further improves joint inversion results.

4. Real data example

We apply our joint inversion scheme to data recorded about 150 km southeast of the Faroe Islands (Fig. 9). This area is characterized by thick sequences of basalt flows that are associated with magmatic activity during the continental break-up of the North Atlantic in the Tertiary (e.g. White et al., 2003; Gallagher and Dromgoole, 2007). The basalt flows overlie sediments accumulated in basins during earlier episodes of stretching of the continental lithosphere from the late Carboniferous to the early Paleocene.

Figure 8: Final results for a joint inversion, which combines the adaptive coupling strategy considering petrophysical information with mutual cross-coupling strategy considering structural information. Starting models for this run are the intermediate results (72 iteration) of the petrophysical inversion, whose results are shown in Figure 6. For this inversion D values are set to 0.7 and resolution estimated are incorporated in the calculation of physical parameter projections.

699 Traps in these Mesozoic sub-basalt sediments are considered as potential
700 hydrocarbon-bearing structures. Underneath the sediments a pre-rifted base-
701 ment is present which probably consists of gneissic rocks and formed during
702 the Caledonian Orogeny.

703 In this area comprehensive geophysical data sets are available for a wide-
704 range of methods. *Statoil*, who manages License L006 (red outline in Fig. 9)
705 in this region, provided us with geophysical data presented here. The data
706 include a pattern of wide-angle seismic lines, a marine 3-D Full Tensor Grav-
707 ity (FTG) survey and a number of MT sites distributed on a 3-D grid. While
708 the data provide 3-D coverage, we limit our investigation to 2-D lines, since
709 *JINV2D* cannot handle 3-D MT data. We therefore focus on the FLA6
710 profile, which crosses the northern part of the license area in WNW-ESE
711 direction (green line in Fig. 9). Hence in the joint inversion presented here
712 we only use seismic data from FLA6 (49093 seismic first arrival times from
713 shot gathers that have offset ranges of 3 to 18km) and gravity (425 locations

714 from a 3-D shipborne survey) and MT data (11 stations with periods from
715 0.0061 to 0.15 s) that are measured in the vicinity of this profile.

716 Data from the individual methods were collected in separate surveys from
717 1995 to 2002 and the acquisition strategies are not optimized for such data
718 integration. MT stations used in our 2-D joint inversion are not located
719 immediately on the seismic profile but lie up to 7 km on either side of it.
720 MT and gravity data only overlap with seismic data in the western and
721 eastern part of the profile (Fig. 9), respectively. In addition to the geophysical
722 data used for the inversion, we received data from a 3-D reflection seismic
723 survey, which has a large overlap with the FLA6 profile in the northern
724 part of the licence, and logging data from the 4200 m deep BRUGDAN well
725 located in the immediate vicinity of the FLA6 profile (red star in Fig. 9).
726 The reflection seismic data allow a direct comparison of the joint inversion
727 results with structures derived independently. We use the logging data (sonic,
728 resistivity and gamma-gamma log) to derive parameter relationships for our
729 joint inversion, which are depth independent.

730 The nearly vertical BRUGDAN borehole penetrates the top basalt and
731 the underlying sediments at 1154m and 3719m below sealevel, respectively
732 (Schuler et al., 2012). Logging data show a distinct increase in P-wave veloc-
733 ities and resistivities across the upper sediment-basalt interface (see Fig. 10).
734 (Although no density data from logging are available above the basalt, it is
735 likely that densities of the basalt are significantly higher than of the shallow
736 sediments.) The possible base of the basalt sequence is however character-
737 ized by a more gradual change in physical parameters. Figures 11a) and b)
738 show cross-plots and we observe that there are positive correlations between

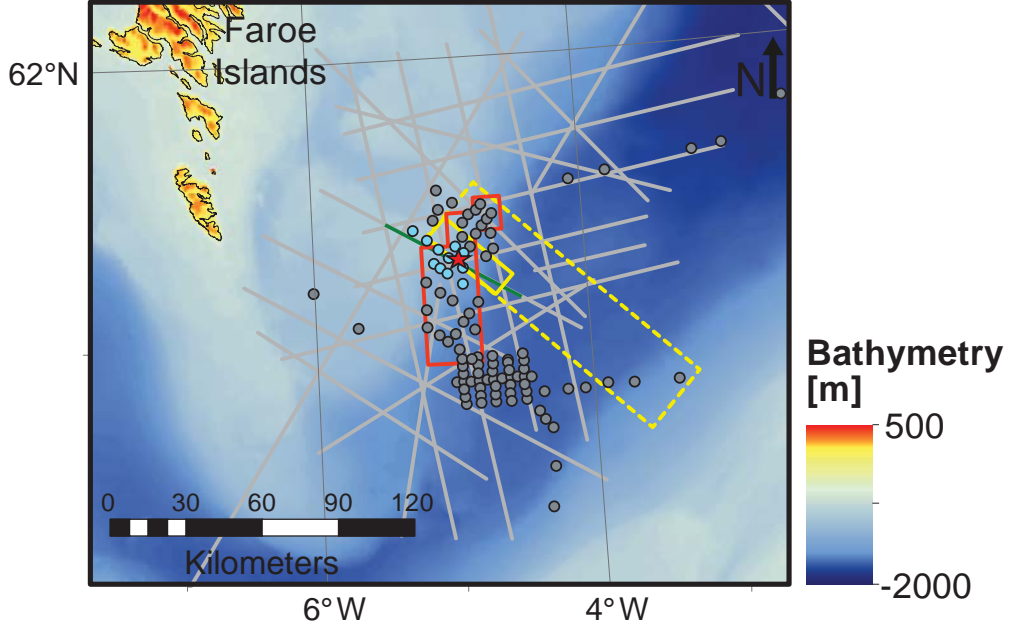

Figure 9: Map of our investigation area in the Faroe-Shetland Basin. A FTG survey (dashed yellow rectangle), several wide angle seismic profiles (grey lines) and MT sites (circles) are present in the region. Data used in our 2-D joint inversion along the seismic profile FLA6 are highlighted (small yellow rectangle, green line and light blue circles correspond to the gravity, seismic and MT data, respectively). Red star indicates the position of the BRUGDAN borehole, red line outline the license area L006.

739 seismic P-wave velocity and resistivity and between P-wave velocity and bulk
 740 density. Such positive v_p - d correlations are present for many subsurface con-
 741 ditions, but positive v_p - ρ correlations are less common and are reported for
 742 fewer **geological** conditions e.g. for sub-basalt regions due to the effect of the
 743 pore space on both v_p and ρ (e.g. Jegen et al., 2009).

744 To estimate adequate parameter relationships for the joint inversion,
 745 curve-fitting in a least-square sense was performed between the physical prop-

erties of the borehole logging data (Fig. 11a)-b)). The analytic expressions
are

$$\log_{10} \rho = 7.876 \cdot 10^{-8} \cdot (v_p)^2 - 0.1512$$

$$d = 0.0001737 \cdot v_p + 1.868$$

for the velocity (in m/s) - resistivity (in Ωm) and velocity (in m/s) - density
(in g/cm^3) relationships, respectively.

Figure 10: Comparison of the logging data from the BRUGDAN borehole and the joint inversion results along the prole FLA6. Blues lines show measured borehole logs and red lines the same data after applying a moving average (filter length = 100 m). Green dots indicate the physical properties obtained from the joint inversion along the borehole drilling (see Fig. 17). Horizontal grey dashed lines indicate top and base basalt as proposed by Schuler et al. (2012).

752 The logging data generally show a large variation of the physical proper-
 753 ties on a sub-metre scale. Cross plots of the physical parameters (Fig. 11)
 754 show that this results in a larger scatter around the fitted relationships and
 755 reveal that for some geological structures rock property links are systemati-
 756 cally shifted (e.g. depth range 2500-3150 m in Fig. 11a-b) such that the fits
 757 are not good representations for these depths ranges. However, if the logging
 758 data are averaged over depths intervals of 100m, which corresponds to the
 759 cells widths in the inversion, the relationships are adequate estimates for the
 760 scale resolvable by the inversions (Fig. 11c-d)).

761 *4.1. Estimation of data errors*

762 It is crucial for our adaptive joint inversion scheme to use realistic data er-
 763 ror estimates, as the coupling strength of a method is strongly dependent on
 764 the level of the associated target misfit (at later iterations when the loop ③ in
 765 Fig. 2 becomes relevant). For seismic and gravity we estimated errors directly
 766 from the available data. For a number of seismic shot gathers first-arrivals
 767 were picked independently by three experienced persons. A meaningful offset
 768 dependent error estimates for all seismic data is derived by considering the
 769 time variations of the three picked onsets for the same traces. For the grav-
 770 ity the data spacing of measurement points in the in-line direction is small
 771 ($\approx 15m$) and the ocean is several hundred meters deep such that variations
 772 with short wavelength can be associated with uncorrelated noise. We there-
 773 fore obtain a proper error estimate ($\sigma^2 = 0.1mgal$) through experimental
 774 *variograms at very small distances ("nugget" effect; see e.g. Dubrule, 2003).*
 775 For MT we only received processed data as frequency dependent impedance
 776 estimates together with some error estimates (determined by a robust pro-

cessing scheme), but not the original time series of the electromagnetic field
 components. Hence, we cannot determine any error estimates ourselves or
 to evaluate the reliability of the error estimates provided. When we perform
 the inversions (both a single MT inversion and the adaptive joint inversion),
 it is not possible to reach the proposed target misfits for MT even with fine
 gridding. Dimensionality analysis indicates that the resistivity distribution
 are either 1-D or 2-D (with the strike oriented perpendicular to the profile
 direction), so 3-D effects can be largely excluded as the cause for high mis-
 fits, which leads us to conclude that errors are generally underestimated.
 We therefore choose for the joint inversion target misfits that are similar to
 the minimum misfits we obtain from single MT inversions. During the joint
 inversion we observe (see discussion below) that coupling parameters of the
 MT are not extremely low for the chosen target misfit and that the results are
 generally meaningful indicating that the chosen target misfit is appropriate.

4.2. *Parameters used for the joint inversion*

The model consists of 68 and 71 inversions cells in x- and z-direction,
 respectively, with a constant cell size of 0.5×0.1 km. Starting models
 for the gravity and MT inversion have constant densities and resistivities
 of $d = 2.5g/cm^3$ and $\rho = 10\Omega m$ below a high conductive and low-density
 layer associated with the seawater column of the ocean. The velocities of
 the seismic starting model gradually increase with depth from $1500m/s$ at
 the sea-bottom to $6000m/s$ at 4000 m depth. As for the synthetic tests,
 the coupling strengths vary adaptively during the joint inversion procedure.
 To control the convergence speed $D^{seis.}$, $D^{grav.}$ and D^{MT} of 0.4 are cho-
 sen and $\tilde{L} = 3$ iterations are used for each method to modify the μ -value

for a subsequent iteration. The coupling parameters at the first iterations are set to $\mu^{seis.} = \mu^{grav.} = \mu^{MT} = 0.25$. The calculation of the projection is governed by resolution estimates as already described above and the regularisation parameters λ are gradually reduced from starting values of $\lambda^{seis.} = \lambda^{grav.} = \lambda^{MT} = 0.25$ by using the method proposed by Lelièvre et al. (2012). Structural cross-coupling is only used for the last iterations (> 60).

4.3. Joint inversion results

The convergence behaviour for all three methods (see Fig. 12) is stable and target misfits for gravity, seismic and MT are reached after 3, 13 and 60 iterations, respectively. Similar observed data and calculated data from the joint inversion (see Figures 13, 14 and 15) indicate that the data are well-fitted for all methods. The final parameter models from this joint inversion run are shown in Fig. 16, Row 2. To evaluate the improvements obtained by using our joint inversion strategy, we perform corresponding separate inversion with similar parameters as for the joint inversion (same starting models, same inversion grid, similar regularization strength). It is obvious that the joint inversion results are more consistent with each other than the results from the individual inversions (compare Row 1 and Row 2 of Fig. 16). In the joint inversion models low v_p , d and ρ values at shallow depths are separated by a sharp boundary from quasi horizontal high velocity, high density and high resistivity anomalies present in a depth range from about 2000 to 4000 m. Below 4000 m the physical parameters gradually decrease again with depth. These anomaly distributions are associated with a basaltic sequence enclosed by sediments above and below. In contrast, the single seismic inversion **resolves** only well the upper sediments and top

827 basalt, but no structures underneath. The single MT inversion creates a
828 mostly horizontal high-resistive layer in the western and central part of the
829 profile that is covered by MT stations. The anomaly is, however, too thick to
830 realistically represent the basaltic sequence. The horizontal density anomaly
831 from the single gravity inversion results is not well resolved and is largely
832 dependent on the chosen starting model.

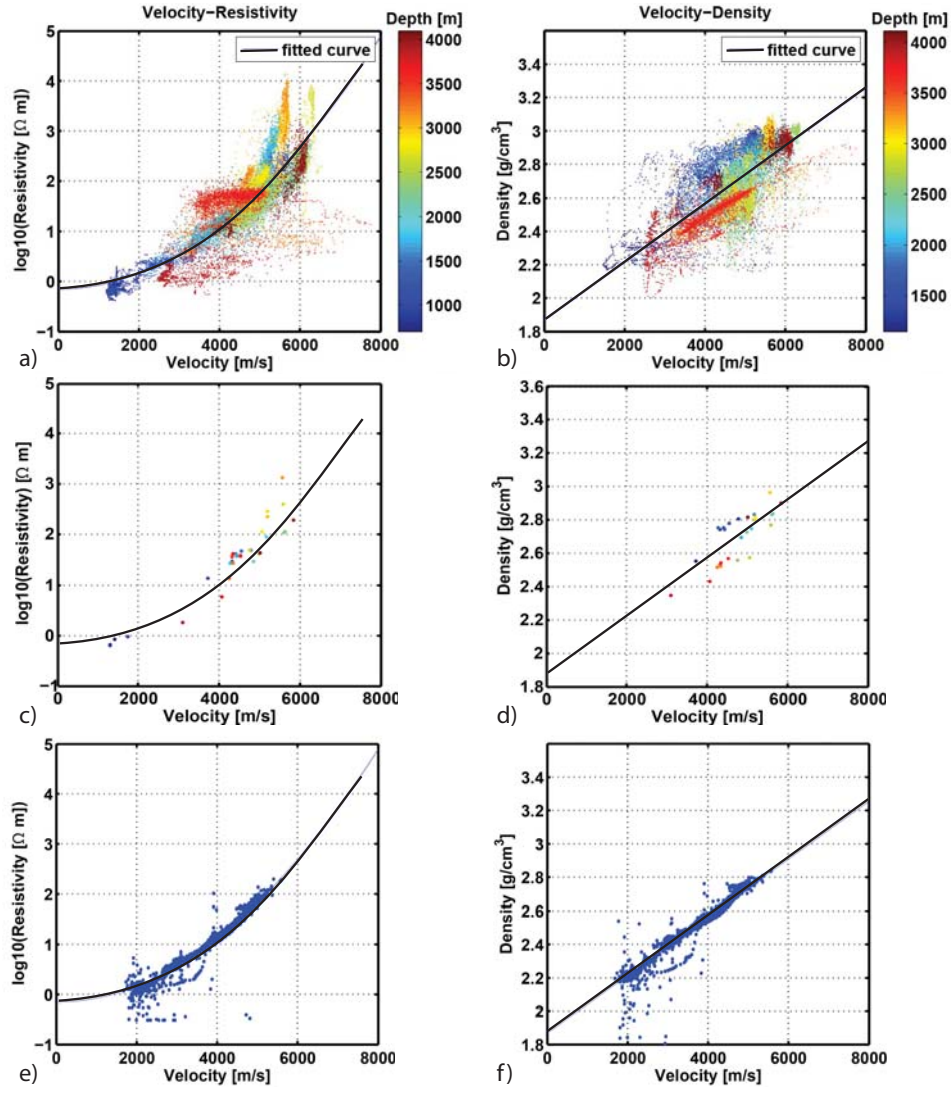

Figure 11: a) and b): Cross plots of the logging data from the borehole BRUGDAN. Color-coding of the dots is associated with the actual depths. c) and d): Mean values of physical properties calculated for 100 meter intervals and presented in the same form as for a) and b). e) and f): Cross plots for the final results of the adaptive joint inversion. Black lines show parameter relationships determined by fitting of logging data, which are used in our joint inversions.

Figure 12: Convergence of our adaptive joint inversion for real data example. Values of data and regularization terms of the objective functions are plotted as continuous and dashed lines, respectively. Seismic data, gravity data and MT data are shown in blue, green and red, respectively. Arrows indicate iterations at which target misfits for the associated methods are reached.

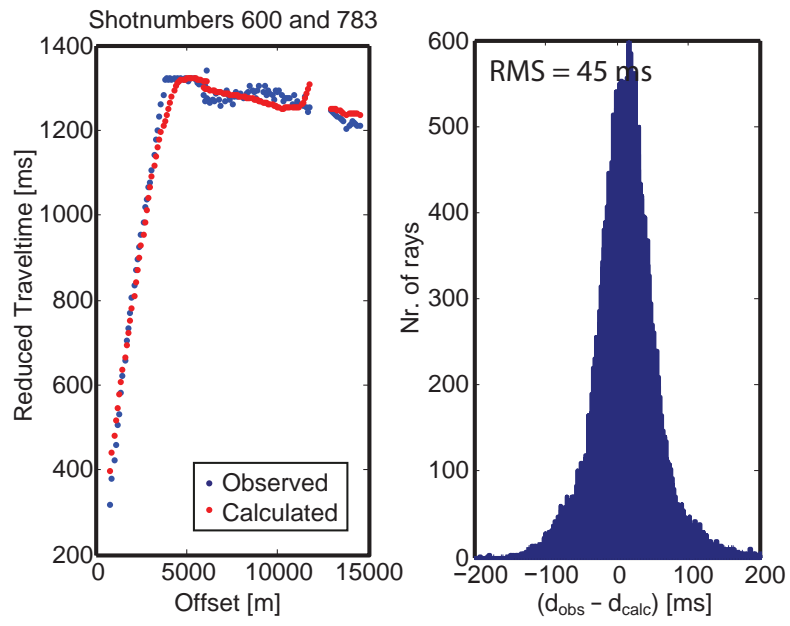

Figure 13: Final seismic data misfits for the adaptive joint inversion. Left: Picked first arrival times (red) for a typical shot gather together with the corresponding calculated traveltimes (blue). Traveltimes in the shot gather are reduced with a velocity of 5000 m/s, Right: Histogram of data misfits from all seismic first arrival times used in joint inversion.

Figure 14: Final gravity data misfits for the adaptive joint inversion. Left: Observed (blue) and calculated (red) gravity responses for all measuring points. Right: Histogram of the gravity data misfits.

Figure 15: Final MT responses obtained from the adaptive joint inversion. Apparent resistivities for all frequencies and stations are shown for the calculated (top panels) and observed (bottom panels) responses for TE mode (left) and TM mode (right) polarization.

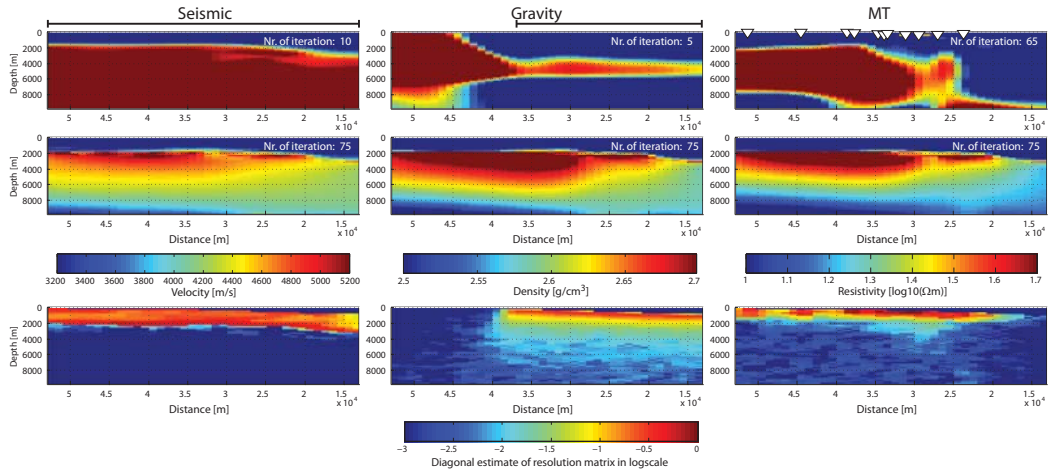

Figure 16: Inversion results and resolution estimates for the seismic, gravity and MT data used for the real data example. First and second row show the results from separate inversions and adaptive joint inversion. Black lines above the velocity model and density model indicate areas, where seismic and gravity data were acquired. Triangles above the resistivity model mark the positions of the marine MT sites. Third row shows approximations of the diagonal elements of the resolution matrices for the final models of the joint inversion (second row).

Although the results from joint inversion are consistent, the total resolution below the top basalt is relatively low for all methods (see diagonal estimates of the resolution matrices in Fig, 16, Row 3). Lack of measurement sites for gravity and MT at the west and east side of the profile result in a strongly reduced resolution in these areas. This indicates that a more complete coverage and the use of other data; e.g. seismic reflection onsets in the seismic (Fliedner and White, 2003) or CSEM (Panzner et al., 2014; Hoversten et al., 2015) could further improve the results particularly at larger depths.

As mentioned above the physical parameter relationships are only estimates which are not valid everywhere and we indeed observe decoupling in some parts. Coupling parameters are with $\mu^{seis.} = 0.0010 - 0.0227$ and $\mu^{MT} = 0.045 - 0.212$ low for seismic and MT at the late iterations (60 to 65) - only $\mu^{grav.}$ has higher values ranging from 0.33 to 0.45, and cross-plots of the physical parameters of the final joint inversion results (Fig. 11e-f) show distinct deviations from the relationships for a number of inversion cells.

To verify our joint inversion results we compare the joint inversion models with 3-D reflection seismic data and borehole data. Since the z-axis of the reflection seismic data set is given in time and not in depth, the final joint inversion models are converted to two-way travel-times by using the velocity model obtained from the joint inversion. In Figure 17 the resultant resistivity model is shown together with the cross-section of the 3-D seismic data cube along the FLA6 profile. Although both, resistivity and the seismic model, have some uncertainty, the top basalt reflection in the seismic data coincides well with the sharp boundary between low resistivities

858 associated with the shallow sediments and high resistivities associated with
 859 the basalt. It demonstrates that joint inversion provides accurate results
 860 in the well-resolved shallow part. Comparison in the deeper part is much
 861 more difficult because both reflection seismic and joint inversion give less
 862 clear results. A distinct seismic reflection associated with the base basalt
 863 is absent, but instead there is a pattern of discontinuous reflections that is
 864 interpreted as the base basalt (see dashed line in Fig. 17). The data from the
 865 bottom of the BRUGDAN borehole (Schuler et al., 2012) and results from
 866 wide-angle seismic studies (Fliedner and White, 2003; Spitzer et al., 2003)
 867 support this interpretation. Resolution of the joint inversion is significantly
 868 reduced at this depth range resulting in smooth changes in the parameter
 869 models. To evaluate if the thickness and, hence, the lower bound of the hor-
 870 izontal anomalies with large physical properties representing the basalt layer
 871 ($v_p > 4500\text{m/s}$ and $\rho > 30\Omega\text{m}$) are reliable, we repeat the joint inversion
 872 with different starting models. Results show that thicknesses of anomalies
 873 are generally stable for most of the western and the central part, but not in
 874 the eastern part which is not covered by MT sites. Comparison of the joint
 875 inversion models with the logging data as a function from depth shows that
 876 the modelled physical parameters are in the same range as the logging data
 877 for both the upper sediments and the basalt, however, variations within the
 878 basaltic sequence are not resolved (Fig. 10).

879 Other studies based on seismic data note that a NE-SW striking structural
 880 high of the pre-rifted basement - the East Faroe High - rises in the vicinity
 881 of the BRUGDAN borehole and the white arrows in Figure 17 may indicate
 882 reflections associated with this structure. However, in the joint inversion

883 model no such structure is observed, which we attribute to the fact that the
 884 resolution of the methods combined in the joint inversion is not high enough
 885 to resolve the deep basement.

Figure 17: The transparent resistivity image from the joint inversion superimposes the cross-section from the 3-D reflection seismic dataset along the FLA6 profile (see Fig. 9). To transfer the depth axis of the resistivity image to two-way-travel times, the final velocity model from the joint inversion is used. Triangles indicate the locations of MT stations and dashed lines show the basalt as proposed by reflections seismic and logging data from the BRUGDAN borehole. Arrows highlight some reflectors associated with the pre-rifted basement.

886 5. Conclusion and Outlook

887 We have demonstrated that critical issues associated with joint inversion
888 algorithms are handled in our joint inversion scheme: 1) a petrophysical joint
889 inversion, in which parameter relationships are considered as constraints, re-
890 quires no relative weighting of the data sets; 2) both for the synthetic tests
891 and in the real data example, we observe that the implemented adaption
892 of the coupling parameters makes the convergence of the individual meth-
893 ods robust and independent of the choice of parameters controlling the joint
894 inversion as the adaption rates D . For all runs with the adaptive joint inver-
895 sion, the target misfits are reached for all methods and results are close to
896 the true models; 3) by considering the spatially dependent resolution power
897 of the individual methods in the coupling constraints, the convergence be-
898 haviour is improved compared to the same joint inversion where resolution
899 estimates are not incorporated; 4) results from the real data example show
900 that the obtained rock property behaviour can deviate from the assumed pa-
901 rameter relationships used as constraints. This happens when the true rock
902 properties are, in parts, not adequately represented by the relationships and
903 a too strong coupling is in disagreement with low data misfits.

904 In addition to these critical issues, we have shown that also structural in-
905 formation can be easily incorporated in this otherwise petrophysically linked
906 joint inversion scheme by adjusting the smoothing constraints by mutual
907 cross-coupling. Such added structural information sharpens parameter bound-
908 aries in parts of the models that are well resolved for some of the geophysical
909 methods used.

910 Application of the adaptive joint inversion scheme on a combined wide-

911 angle seismic, MT and gravity data set that was acquired offshore the Faroe
 912 Islands, a region that is characterized by large-scaled flood basalt, demon-
 913 strates that this joint inversion works reliably also for real data and provides
 914 more consistent results than individual inversions. However, the same results
 915 indicate that even the combination of these methods is unable to adequately
 916 resolve deep structures such as thickness of the sub-basalt sediments and the
 917 pre-rifted basement. This is not directly related to our joint inversion strat-
 918 egy but to the low resolution power of the methods in the deeper subsurface.
 919 To resolve sub-basalt structures more complete coverage and possibly other
 920 geophysical data are required. For example we recommend to use reflection
 921 events in the seismic tomography and to add CSEM as another electromag-
 922 netic method (Panzner et al., 2014; Hoversten et al., 2015) in the future.

923 6. ACKNOWLEDGMENTS

924 We thank *Wintershall* and the *SINDRI* consortium for sponsoring the
 925 research position of Björn Heincke and part of this project (project num-
 926 ber C46-54-01). We thank Bernd Lahmeyer (*Statoil*, Stavanger), Christian
 927 Berndt (*GEOMAR*, Kiel) and an anonymous reviewer for helpful comments.
 928 David Bösing (*Baker & Hughes*, Celle) supported this work by evaluating dif-
 929 ferent resolution estimates. *Statoil* provided us the field data used in this
 930 study.

931 Appendix A. Projection method

932 Given a point P , consisting of the n physical parameters $m^{(1)}, \dots, m^{(n)}$, we
 933 use an iterative method to determine a projection $\tilde{P} = (\tilde{m}^{(1)}, \dots, \tilde{m}^{(n)})$ onto a

934 pre-defined relationship curve. Convergence of this method is assured as long
 935 as the relationship curve is strictly monotonic. Although only two physical
 936 parameters are used in the following example (Fig. A.18), we emphasize that
 937 the method is in general not limited by the number of considered physical
 938 parameters.

939 In the first iteration of the procedure, lines parallel to the x - and y -axis
 940 that pass through the point $P = (m^{(1)}, m^{(2)})$ are determined (Fig. A.18a).
 941 For these lines, the points of intersection $A = (m_{A,1}^{(1)}, m_{A,1}^{(2)})$ and $B = (m_{B,1}^{(1)}, m_{B,1}^{(2)})$
 942 with the relationship curve are determined and the mean values $m_{AB,1}^{(1)} =$
 943 $\frac{m_{A,1}^{(1)} + m_{B,1}^{(1)}}{2}$ and $m_{AB,1}^{(2)} = \frac{m_{A,1}^{(2)} + m_{B,1}^{(2)}}{2}$ are calculated. For the next iteration
 944 axis parallel lines passing through $m_{AB,1}^{(1)}$ and $m_{AB,1}^{(2)}$ are then used to de-
 945 termine new points of intersection with the relationship curve $(m_{A,2}^{(1)}, m_{A,2}^{(2)})$
 946 and $(m_{B,2}^{(1)}, m_{B,2}^{(2)})$ (Fig. A.18b). From these points again the mean values
 947 $m_{AB,2}^{(1)} = \frac{m_{A,2}^{(1)} + m_{B,2}^{(1)}}{2}$ and $m_{AB,2}^{(2)} = \frac{m_{A,2}^{(2)} + m_{B,2}^{(2)}}{2}$ are determined.

948 At every iteration the two points of intersection converge against each
 949 other. If the distance between the intersections points becomes smaller than
 950 a pre-defined threshold value at the t -th iteration the procedure is stopped.
 951 The mean values of the points of intersection $(\frac{m_{A,t}^{(1)} + m_{B,t}^{(1)}}{2}, \frac{m_{A,t}^{(2)} + m_{B,t}^{(2)}}{2})$ is then
 952 considered as the projection point $\tilde{P} = (\tilde{m}^{(1)}, \tilde{m}^{(2)})$.

953 Because $m_{AB}^{(1)}$ and $m_{AB}^{(2)}$ depend on variations of the first and second phys-
 954 ical parameter, respectively, the influence of the different parameters is in-
 955 herently balanced and, hence, more or less independent of employed units
 956 and slope of the relationship curve.

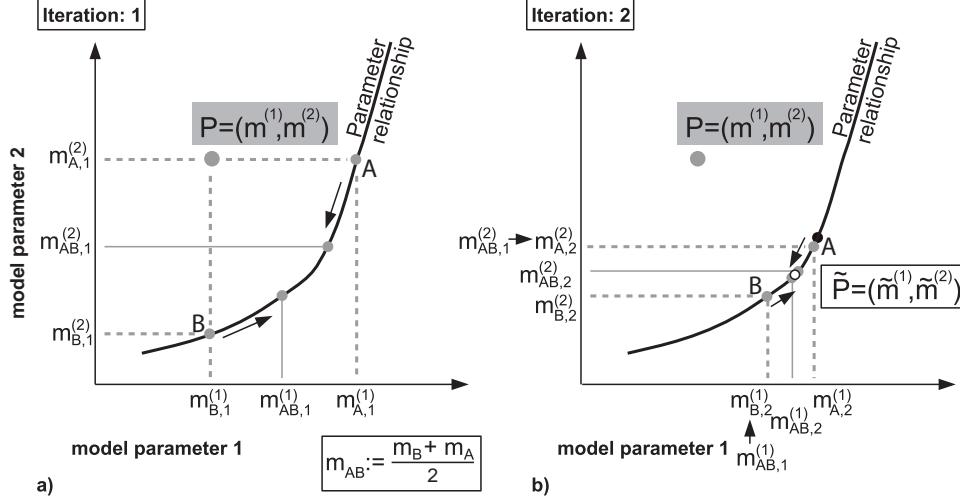

Figure A.18: Sketch illustrating the iterative procedure to determine for a point of two physical parameters $m^{(1)}$ and $m^{(2)}$ a projection $(\tilde{m}^{(1)}, \tilde{m}^{(2)})$ onto a relationship curve. (a) and (b) show the 1st and 2nd iteration step of the procedure assuming that both parameters are equally weighted. The white and black dot in b) show the obtained projection point if the same weights and different weights of $\psi = 1.0$ and $\phi = 0.5$ are considered for the two parameters (see Appendix B), respectively.

957 Appendix B. Modification of the projection to account for the 958 model resolutions

959 The general procedure is the same as already described as in the Appendix
960 A. However, the sums $m_{AB,t}^{(1)}$ and $m_{AB,t}^{(2)}$ are now calculated by some weighted
961 mean values. In the case of having two parameters and using the diagonal
962 elements $d^{(1)}$ and $d^{(2)}$ of the resolution matrix as measures, they are obtained
963 as:

$$\begin{aligned}
m_{AB,t}^{(1)} &= \frac{\psi m_{A,t}^{(1)} + \phi m_{B,t}^{(1)}}{|\psi| + |\phi|} \\
m_{AB,t}^{(2)} &= \frac{\psi m_{A,t}^{(2)} + \phi m_{B,t}^{(2)}}{|\psi| + |\phi|} \\
\text{with } \psi &= 1.0 - |1.0 - d^{(1)}| \quad \text{if } \gamma \leq d^{(1)} \leq 2.0 \\
&\quad \psi = \gamma \quad \text{otherwise} \\
\text{with } \phi &= 1.0 - |1.0 - d^{(2)}| \quad \text{if } \gamma \leq d^{(2)} \leq 2.0 \\
&\quad \phi = \gamma \quad \text{otherwise}
\end{aligned}$$

964 γ is a small positive value (we use in all test $\gamma = 0.002$) that is intro-
965 duced to make the determination of the projection direction less sensitive
966 to inaccurate calculation of the diagonal element estimates of the resolution
967 matrix.

968 The black dot in Figure A.18b shows the projection point for weights of
969 $\psi = 1.0$ and $\phi = 0.5$.
